# tutorial Spoint

www.tutorialspoint.com

#### **About the Tutorial**

Python is a general-purpose interpreted, interactive, object-oriented, and high-level programming language. It was created by Guido van Rossum during 1985 – 1990. Like Python-the snake. Perl, Python source code is also available under the GNU General Public License (GPL). Python is named after a TV Show called 'Monty Python's Flying Circus' and not after

incompatibles, later on many of its important features have been backported to be compatible with the version 2.7. This tutorial gives enough understanding on Python 3 version programming language. Please refer to this link for our Python 2 tutorial. Python 3.0 was released in 2008. Although this version is supposed to be backward

#### **Audience**

This tutorial is designed for software programmers who want to upgrade their Python skills to Python 3. This tutorial can also be used to learn Python programming language from

#### **Prerequisites**

understanding of any of the programming languages is a plus. You should have a basic understanding of Computer Programming terminologies. A basic

# Execute Python Programs

of it and enjoy your learning. For most of the examples given in this tutorial you will find **Try it** option, so just make use

sample code box -Try the following example using **Try it** option available at the top right corner of the below

```
print ("Hello, Python!")
                                                                 #!/usr/bin/python3
```

# Python 3 **Basic Tutorial**

# Python 3 – What is New?

## The \_\_future\_\_ module

Python 3.x introduced some Python 2-incompatible keywords and features that imported via the in-built \_\_future\_\_ module in Python 2. It is recommended future\_ imports, if you are planning Python 3.x support for your code ç can be use

following import statement. For example, if we want Python 3.x's integer division behavior in Python 2, add the

```
from __future__ import division
```

#### The print Function

Use of parenthesis () with print function is now mandatory. It was optional in Python 2. Most notable and most widely known change in Python 3 is how the **print** function is used

```
print ("Hello World") # in Python 3, print must be followed by
                                                                 print "Hello World" #is acceptable in Python 2
```

suppressed newline. The print() function inserts function inserts a new line at the end, by default. In Python 2, by putting ',' at the end. In Python 3, "end=' '" appends space instead of it can be

```
print(x, end="
   ٿ
     #
                             # Trailing comma suppresses newline in Python 2
  Appends a space instead of
   a newline in Python
```

# Reading Input from Keyboard

Python 2 has two versions of input functions, **input()** and **raw\_input()**. The input() function treats the received data as string if it is included in quotes " or "", otherwise the data is treated as number.

treated as string. In Python 3, raw\_input() function is deprecated. Further, the received data is always

```
10
                           >>> x=input('something:')
                                                                                                            something:10 #entered data is treated as number
                                                                                                                                      >>> x=input('something:')
something:'10'
                                                                                                                                                                 In Python 2
   #eentered data
   İS
   treated
  as string
```

```
"'10'"
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                >> ×
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     >
NameError: name 'raw_input'

                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   treated
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    as
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              string even without ''
```

#### Integer Division

In Python 2, the result of division of two integers is rounded to the nearest integer. A result, 3/2 will show 1. In order to obtain a floating-point division, numerator denominator must be explicitly used as float. Hence, either 3.0/2 or 3/2.0 or 3.0/2.0 will result in 1.5 As 9

Python 3 evaluates 3/2 as 1.5 by default, which is more intuitive for new programmers.

## Unicode Representation

Python 2 requires you to mark a string with a  $\mathbf{u}$  if you want to store it as Unicode

byte classes: byte and byte arrays. Python 3 stores strings as Unicode, by default. We have Unicode (utf-8) strings, and 2

# xrange() Function Removed

the items in the range when needed, saving memory. In Python 2 range() returns a list, and xrange() returns an object that will only generate

In Python 3, the range() function is removed, and xrange() has been renamed as range(). In addition, the range() object supports slicing in Python 3.2 and later .

#### raise exception

Python 2 accepts both notations, the 'old' and the 'new' syntax; Py SyntaxError if we do not enclose the exception argument in parenthesis. syntax; Python ω raises ۵

```
raise IOError("file error") #this is the recommended syntax in Python 3
                                          raise IOError,
                                                                                    IOError("file error")
                                                                                                                            IOError,
                                           "file error"
                                                                                                                              "file error"
                                                                                  #This is also accepted in Python 2
                                          #syntax error is raised in Python 3
                                                                                                                              #This is accepted in Python 2
```

# **Arguments in Exceptions**

In Python 3, arguments to exception should be declared with 'as' keyword.

```
except Myerror as err:
                                     except Myerror, err: # In Python2
 #In Python
```

# next() Function and .next() Method

function, to iterate over generator object, is also accepted. In Python 3, however, next(0 as a generator method is discontinued and raises AttributeError. In Python 2, next() as a method of generator object, is allowed. In Python 2, the next()

```
gen = (letter for letter in 'Hello World') # creates generator object
next(my_generator) #allowed in Python 2 and Python 3
```

#### 2to3 Utility

It reads Python 2.x source code and applies a series of fixers to transform it into a valid Along with Python 3 interpreter, Python 3.x code 2to3.py script is usually installed in tools/scripts folder.

```
Here is a sample Python
                                                        def area(x,y=3.14):
                  print a
                                     a=y*x*x
return a
                                                                              2
                                                                             code (area.py):
```

```
print("area",a)
                  a=area(10)
                                                                                                   def area(x, y=3.14): # formal parameters
                                                                                                                         Converted code :
                                                                                                                                             $2to3 -w area.py
                                                                                                                                                                 To convert into Python 3 version:
                                                                                                                                                                                    print "area",a
                                                                                                                                                                                                      a=area(10)
                                                                               a=y*x*x
                                                            print (a)
                                        return a
```

# Python 3 – Overview

Python is a high-level, interpreted, interactive and object-oriented scripting language. Python is designed to be highly readable. It uses English keywords frequently whereas the other languages use punctuations. It has fewer syntactical constructions than

- not need to compile your program before executing it. Python is Interpreted: Python is processed at runtime by the interpreter. You do This is similar to PERL and
- the interpreter directly to write your programs. Python is Interactive: You can actually sit at a Python prompt and interact with
- Python is Object-Oriented: Python supports Object-Oriented style or technique programming that encapsulates code within objects
- from simple text processing to WWW browsers to games. **Python is a Beginner's Language:** Python is a great language for the beginner-level programmers and supports the development of a wide range of applications

#### History of Python

National Research Institute for Mathematics and Computer Science in the Netherlands Python was developed by Guido van Rossum in the late eighties and early nineties at the

- Python is derived from many other languages, including ABC, Modula-3, C, C++, Algol-68, SmallTalk, and Unix shell and other scripting languages.
- Python is copyrighted. Like Perl, Python source code is now available under the GNU General Public License (GPL).
- Python is now maintained by a core development team at the institute, although Guido van Rossum still holds a vital role in directing its progress
- Python 2.7.11 is the latest edition of Python 2. 1.0 was released in November 1994. In 2000, Python 2.0 was released
- preferably only one -- obvious way to do it." Python 3.5.1 is the latest version of Meanwhile, Python 3.0 was released in 2008. Python 3 is not backward compatible programming constructs with Python 2. The emphasis in Python 3 had been on the removal of duplicate and modules so that "There should be one

#### Python Features

Python's features include-

- syntax. This allows a student to pick up the language quickly. Easy-to-learn: Python has few keywords, simple structure, and a clearly defined
- Easy-to-read: Python code is more clearly defined and visible to the eyes
- Easy-to-maintain: Python's source code is fairly easy-to-maintain
- platform compatible on UNIX, Windows, and Macintosh. A broad standard library: Python's bulk of the library is very portable and cross-
- interactive testing and debugging of snippets of code. Interactive Mode: Python has support for an interactive mode, which allows
- Portable: Python can run on a wide variety of hardware platforms and has same interface on all platforms.
- Extendable: You can add low-level modules modules enable programmers to add to or customize to the Python interpreter. their tools to be These more
- Databases: Python provides interfaces to all major commercial databases
- ported to many system calls, libraries and windows systems, such as Windows MFC, **GUI Programming:** Python supports Macintosh, and the X Window system of Unix. **GUI** applications that can be created and
- shell scripting. Scalable: Python provides a better structure and support for large programs than

are listed below-Apart from the above-mentioned features, Python has a big list of good features. A few

- It supports functional and structured programming methods as well as OOP
- large applications It can be used as a scripting language or can be compiled to byte-code for building
- provides very high-level dynamic data types and supports dynamic type
- It supports automatic garbage collection.
- It can be easily integrated with C, C++, COM, ActiveX, CORBA, and Java

# 3. Python 3 — Environment Setup

#### Try it Option Online

reading and will enable you to verify the programs with different options. Feel free to execute all the available examples online. It will give you the confidence in what you are modify any example and execute it online We have set up the Python Programming environment online, so that you can compile and

Try the following example using our online compiler available at CodingGround

```
print ("Hello, Python!")
                                 #!/usr/bin/python3
```

code sections, at the top right corner that will take you to the online compiler. Just use it and enjoy your learning. For most of the examples given in this tutorial, you will find a **Try it** option on our website

Python 3 is available for Windows, Mac OS and most of the flavors of Linux operating has not been made available for them or has been dropped. system. Even though Python 2 is available for many other OSs, Python 3 support either

# Local Environment Setup

version is installed terminal window and type "python" to find out if it is already installed and which

#### Getting Python

#### Windows platform

Binaries of latest version of Python 3 (Python 3.5.1) are available on this download page

The following different installation options are available.

- Windows x86-64 embeddable zip file
- Windows x86-64 executable installer
- Windows x86-64 web-based installer
- Windows x86 embeddable zip file
- Windows x86 executable installer
- Windows x86 web-based installer

For versions 3.0 to 3.4.x, Windows XP is acceptable. Note: In order to install Python 3.5.1, minimum OS requirements are Windows 7 with SP1.

#### Linux platform

Different flavors of Linux use different package managers for installation of new packages.

On Ubuntu Linux, Python 3 is installed using the following command from the terminal

```
$sudo apt-get install python3-minimal
```

Installation from source

```
tar xvfz Python-3.5.1.tgz
sudo make
                                                       ./configure
                                                                                            cd Python-3.5.1
                                                                                                                           Configure and Install:
                                                                                                                                                                                                                         https://www.python.org/ftp/python/3.5.1/Python-3.5.1.tgz
                                                                                                                                                                                                                                             Download Gzipped source
                                                                                                                                                                                          the
install
                                                         --prefix=/opt/python3.5.1
                                                                                                                                                                                          tarball
                                                                                                                                                                                                                                               tarball
                                                                                                                                                                                                                                              from Python's download URL:
```

#### Setting up PATH

systems provide a search path that lists the directories that it searches for executables. Programs and other executable files can be in many directories. Hence, the operating

The important features are-

by the operating system. This variable The path is stored in an environment variable, which is a named string maintained command shell and other programs. contains information available to the

- sensitive; Windows is not). The path variable is named as PATH in Unix or Path in Windows (Unix is case-
- from any particular directory, you must add the Python directory to your path. In Mac OS, the installer handles the path details. To invoke the Python interpreter

# Setting Path at Unix/Linux

To add the Python directory to the path for a particular session in Unix-

- Enter. In the csh shell: type setenv PATH "\$PATH:/usr/local/bin/python3" and press
- and press Enter. In the bash shell (Linux): type export PATH="\$PATH:/usr/local/bin/python3"
- In the sh or ksh shell: type PATH="\$PATH:/usr/local/bin/python3" and press

Note: /usr/local/bin/python3 is the path of the Python directory.

## **Setting Path at Windows**

To add the Python directory to the path for a particular session in Windows

At the command prompt: type

path %path%;C:\Python and press Enter.

**Note:** C:\Python is the path of the Python directory.

# Python Environment Variables

Here are important environment variables, which are recognized by Python-

It contains the path of an initialization file containing Python start the interpreter. It

PYTHONCASEOK	It is used in Windows to instruct Python to find the first case-insensitive match in an import statement. Set this variable to any value to activate it.
PYTHONHOME	It is an alternative module search path. It is usually embedded in the PYTHONSTARTUP or PYTHONPATH directories to make switching module libraries easy.

#### Running Python

There are three different ways to start Python-

## (1) Interactive Interpreter

You can start Python from Unix, DOS, or any other system that provides you a command-line interpreter or shell window.

Enter **python** the command line.

Start coding right away in the interactive interpreter.

C:>python	0r	python%	07	\$python
# Windows/DOS		# Unix/Linux		# Unix/Linux

Here is the list of all the available command line options-

-c cmd	- <b>X</b>	ν-	-S	-0	p-	Option
run Python script sent in as cmd string	disable class-based built-in exceptions (just use strings); obsolete starting with version 1.6	verbose output (detailed trace on import statements)	do not run import site to look for Python paths on startup	generate optimized bytecode (resulting in .pyo files)	provide debug output	Description

file
Ø
run Python script from given file

# (2) Script from the Command-line

application, as shown in the following example. A Python script can be executed at the command line by invoking the interpreter on your

\$python script.py	# Unix/Linux
Or	
python% script.py	# Unix/Linux
Or	
C:>python script.py	# Windows/DOS

**Note:** Be sure the file permission mode allows execution.

# (3) Integrated Development Environment

a GUI application on your system that supports Python. You can run Python from a Graphical User Interface (GUI) environment as well, if you have

- Unix: IDLE is the very first Unix IDE for Python.
- a GUI. Windows: PythonWin is the first Windows interface for Python and is an IDE with
- from the main website, downloadable as either MacBinary or BinHex'd files. Macintosh: The Macintosh version of Python along with the IDLE IDE is available

system admin. Make sure the Python environment is properly set up and working perfectly If you are not able to set up the environment properly, then you can take the help of your

version available on Windows 7 and Ubuntu Linux. Note: All the examples given in subsequent chapters are executed with Python 3.4.1

example and execute it online. all the available examples online while you are learning theory. Feel free to modify any We have already set up Python Programming environment online, so that you can execute

# Python 3 — Basic Syntax

The Python language has many similarities to Perl, C, and Java. However, there are some definite differences between the languages.

## First Python Program

Let us execute the programs in different modes of programming

# **Interactive Mode Programming**

Invoking the interpreter without passing a script file as a parameter brings up the following

```
Python 3.4.3 (v3.4.3:9b73f1c3e601, Feb 24 2015, 22:43:06) [MSC v.1600 32 bit (Intel)] on
                                                                                           On Windows:
                                                                                                                                                                                                                               Python 3.3.2 (default,
                                                                                                                                                                                                                                                               $ python
Type "copyright",
                                                                                                                                                           Type "help",
                                                                                                                                                                                            [GCC 4.6.3] on Linux
                                                                                                                                                           "copyright",
 "credits"
                                                                                                                                                                                                                             Dec 10 2013, 11:35:01)
                                                                                                                                                            "credits", or "license"
or "license()"
for more information
                                                                                                                                                             for more information.
```

Type the following text at the Python prompt and press Enter-

```
>>> print ("Hello, Python!")
```

inprint function is optional. This produces the following result-If you are running the older version of Python (Python 2.x), esu 앜 parenthesis as

```
Hello,
Python!
```

## **Script Mode Programming**

active continues until the script is finished. When the script is finished, the interpreter is no longer the interpreter with a script parameter begins execution of the script and

the following source code in Let us write a simple Python program in a script. Python files have the extension.py. Type a test.py file-

```
print ("Hello, Python!")
```

this program as follows-We assume that you have the Python interpreter set in PATH variable. Now, try to run

#### On Linux

```
$ python test.py
```

This produces the following result-

Hello, Python!

#### On Windows

```
C:\Python34>Python test.py
```

This produces the following result-

```
Hello, Python!
```

file-Let us try another way ð execute a Python script in Linux. Here S the modified test.py

```
print ("Hello, Python!")
                                 #!/usr/bin/python3
```

to run this program as follows-We assume that you have Python interpreter available in the /usr/bin directory. Now, try

```
$./test.py
               chmod +x test.py
                #
               This is
                ç
                make
                file executable
```

This produces the following result-

```
Hello, Python!
```

#### Python Identifiers

object. An identifier starts with a letter A to Z or a to z or an underscore  $(\_)$  followed by zero or more letters, underscores and digits (0 to 9). A Python identifier is a name used to identify a variable, function, class, module or other

Python is a case sensitive programming language. Thus, **Manpower** and **manpower** are two different identifiers in Python.

Here are naming conventions for Python identifiers-

- lowercase letter. Class names start with an uppercase letter. All other identifiers start with a
- Starting an identifier with a single leading underscore indicates that the identifier is private

- Starting an identifier with two leading underscores indicates identifier. ۵ strong private
- defined special name. If the identifier also ends with two trailing underscores, the identifier is a language-

#### **Reserved Words**

The following list shows the Python keywords. These are reserved words and you cannot use them as constants or variables or any other identifier names. All the Python keywords contain lowercase letters only.

except	else	elif	del	def	continue	class	break	assert	as	and
	lambda	is	in	import	if	global	from	for	finally	exec
	yield	with	while	try	return	raise	print	pass	or	Not

## Lines and Indentation

Python does not use  $braces(\{\})$  to indicate blocks of code for class and function definitions flow control. Blocks of code are denoted by line indentation, which is rigidly enforced.

must be indented the same amount. For example-The number of spaces in the indentation is variable, but all statements within the block

```
÷
print ("False")
                              print ("True")
```

However, the following block generates an error-

```
print ("False")
                                                                                        True:
                                                 print ("True")
                  print "(Answer")
                                                                   print ("Answer")
```

form a block. The following example has various statement blocks-Thus, in Python all the continuous lines indented with the same number of spaces would

**Note:** Do not try to understand the logic at this point of time. Just make sure you understood the various blocks even if they are without braces.

```
if len(file_name) == 0:
                                                             file_name = input("Enter filename: ")
                                                                                                                                                                                                                                                                                                                                                                                                                                       print ("Enter '", file_finish,)
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                 #!/usr/bin/python3
                                                                                                  file.close()
                                                                                                                                                                                                                                                                                                                                                                        while file_text != file_finish:
                                                                                                                                                                                                                                                                                                                                                                                                         print "' When finished"
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                               except IOError:
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                 import sys
print ("Next time please enter something")
                                                                                                                                 file.write("\n")
                                                                                                                                                                     file.write(file_text)
                                                                                                                                                                                                                                                                                                    if file_text ==
                                                                                                                                                                                                                                                                                                                                     file_text = raw_input("Enter text: ")
                                                                                                                                                                                                                                                                                                                                                                                                                                                                            sys.exit()
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                         print ("There was an error writing to", file_name)
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          file = open(file_name, "w")
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              # open file stream
                                                                                                                                                                                                                                                                      # close the file
                                                                                                                                                                                                                                       file.close
                                                                                                                                                                                                                                                                                                       file_finish:
```

```
print (file_text)
                               file.close()
                                                          file_text = file.read()
                                                                                                                                                except IOError:
                                                                                                                                                                              file
                                                                                        sys.exit()
                                                                                                                   print ("There was an error reading file")
                                                                                                                                                                                                                                    sys.exit()
                                                                                                                                                                         = open(file_name, "r")
```

## Multi-Line Statements

Statements in Python typically end with a new line. Python, however, allows the use of the line continuation character ( $\setminus$ ) to denote that the line should continue. For example-

```
item_one
item_three
              item_two +
```

The statements contained within the [], continuation character. For example- $\Leftrightarrow$ or () brackets do not need to use the line

```
days = ['Monday', 'Tuesday', 'Wednesday',
'Thursday', 'Friday']
```

#### Quotation in Python

as long as the same type of quote starts and ends the string. Python accepts single ('), double (") and triple ("' or """) quotes to denote string literals,

following are legal-The triple quotes are used to span the string across multiple lines. For example, all the

```
paragraph = """This is a paragraph.
                                                                                  word = 'word'
 made up of multiple
                                                      sentence = "This is
  lines
                                                    a sentence."
and sentences."""
                             It is
```

## Comments in Python

A hash sign (#) that is not inside a string literal is the beginning of a comment. All characters after the #, up to the end of the physical line, are part of the comment and the Python interpreter ignores them. ₽

```
#!/usr/bin/python3
```

```
print ("Hello, Python!") #
                    First comment
 second
 comment
```

This produces the following result-

```
Hello, Python!
```

You can type a comment on the same line after а statement or expression-

```
name
"Madisetti"
 #
 This
15
again
comment
```

Python does not have multiple-line commenting feature. You have individually as followsto comment each line

```
This is a comment, too.
                                                         This is a comment, too.
I said that already.
                                                                                         is a comment.
```

#### **Using Blank Lines**

Python totally ignores it. A line containing only whitespace, possibly with a comment, is known as a blank line and

a multiline statement. In an interactive interpreter session, you must enter an empty physical line to terminate

#### Waiting for the User

The following line of the program displays the prompt and the statement saying "Press the enter key to exit", and then waits for the user to take action —

```
#!/usr/bin/python3
input("\n\nPress the enter key
 to exit.")
```

until the user is done with an application. user presses the key, the program ends. This is a nice trick to keep a console window open Here, " $\n$ " is used to create two new lines before displaying the actual line. Once the

# Multiple Statements on a Single Line

The semicolon (;) allows multiple statements on a single line given starts a new code block. Here is a sample snip using the semicolon-The semicolon (; that no statement

```
import sys;
 ×
  П
'foo'; sys.stdout.write(x + '\n')
```

# Multiple Statement Groups as Suites

Groups of individual statements, which make a single code block are called Python. Compound or complex statements, such as if, while, def, and class header line and a suite. require suites a

are followed by one or more lines which make up the suite. For example Header lines begin the statement (with the keyword) and terminate with a colon ( : ) and

```
elif expression:
                               suite
suite
                                                               suite
                                                                              expression:
```

# Command Line Arguments

should be run. Python enables you to do this with -h: Many programs can be run to provide you with some basic information about how they

```
usage: python [option] ...
                                                                                   н
                                                                                                                               ٩
                                                                                                                                                                                                              Options and arguments (and corresponding environment variables):
                                                                                                                                                                                                                                                                                                    $ python -h
[ etc.
                                                                                                                                                                    -c cmd : program passed in
                                                                                                                          debug output from parser (also PYTHONDEBUG=x)
                                      print this help message and exit
                                                                                  ignore environment variables (such as PYTHONPATH)
                                                                                                                                                                    as string (terminates option list)
                                                                                                                                                                                                                                                        [-c cmd | -m mod | file | -] [arg] ...
```

options. Command Line Arguments is can also program your script in an advance topic. such മ way Let us understand it. that it should accept various

# **Command Line Arguments**

arguments. Python provides a **getopt** module that helps you parse command-line options and

```
python test.py arg1 arg2
arg3
```

the **sys.argv**. This serves two purposes-Python **sys** module provides access ç any command-line arguments ≤ a

- sys.argv is the list of command-line arguments
- len(sys.argv) is the number of command-line arguments

Here sys.argv[0] is the program i.e. the script name.

#### Example

Consider the following script test.py-

```
print ('Argument List:', str(sys.argv))
                                                print ('Number of arguments:', len(sys.argv), 'arguments.')
                                                                                                                                                            #!/usr/bin/python3
```

Now run the above script as follows -

```
python test.py arg1 arg2 arg3
```

This produces the following result-

```
Number of
Argument
 List:
              arguments:
['test.py',
              4 arguments.
'arg1',
'arg2',
 'arg3']
```

being counted in number of arguments NOTE: As mentioned above, the first argument is always the script name and it S also

# Parsing Command-Line Arguments

argument parsing. arguments. This module provides two functions and an exception to enable command line Python provided a **getopt** module that helps you parse command-line options and

#### getopt.getopt method

syntax for this method-This method parses the command line options and parameter list. Following is a simple

```
getopt.getopt(args, options, [long_options])
```

Here is the detail of the parameters-

- args: This is the argument list to be parsed.
- options that require an argument should be followed by a colon (:). options: This is the string of option letters that the script wants to recognize, with
- options, which require an argument should be followed by an equal sign ('='). To accept only long options, options should be an empty string. strings with the names of the long options, which should be supported. Long long\_options: This is an optional parameter and if specified, must be a list of
- option list was stripped. This method returns a value consisting of two elements- the first is a list of (option, value) pairs, the second is a list of program arguments left after the

with a hyphen for short options (e.g., '-x') or two hyphens for long options (e.g., '-Each option-and-value pair returned has the option as its first element, prefixed -long-option').

# **Exception getopt.GetoptError**

requiring an argument is given none. This is raised when an unrecognized option is found in the argument list or when an option

attributes **msg** and **opt** give the error message and related option. The argument to the exception is a string indicating the cause of the error. The

#### Example

Suppose we want to pass two file names through command line and we also want to give an option to check the usage of the script. Usage of the script is as follows-

```
usage: test.py -i <inputfile> -o <outputfile>
```

Here is the following script to test.py-

```
ή
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                               def main(argv):
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                               import sys, getopt
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  #!/usr/bin/python3

                                                                                                                                                                                                                                                                                                     print ('test.py -i <inputfile> -o <outputfile>')
                                _main___":
                                                                                                                                                                                                                                        "--ifile"):
                                                                , outputfile)
```

Now, run the above script as follows-

```
Output file is " outputfile
                                      Input file is " inputfile
                                                                           $ test.py -i inputfile -o outputfile
                                                                                                                 usage: test.py -i <inputfile> -o <outputfile>
                                                                                                                                                    $ test.py -i BMP -o
                                                                                                                                                                                            usage: test.py -i <inputfile> -o <outputfile>
                                                                                                                                                                                                                                  $ test.py -h
```

# 5. Python 3 — Variable Types

you create a variable, you reserve some space in the memory. Variables are nothing but reserved memory locations to store values. It means that when

can be stored in the reserved memory. Therefore, by assigning different data types to the Based on the data type of a variable, the interpreter allocates memory and decides what variables, you can store integers, decimals or characters in these variables.

# **Assigning Values to Variables**

to assign values to variables. happens automatically when you assign a value to a variable. The equal sign (=) is used Python variables do not need explicit declaration to reserve memory space. The declaration

the right of the = operator is the value stored in the variable. For example-The operand to the left of the = operator is the name of the variable and the operand to

```
print (name)
             print (miles)
                            print (counter)
                                                                                          #!/usr/bin/python3
                                              II
                                            "John"
                                                            1000.0
                                             #
                                                            #
                                                                          #
                                                           A floating point
                                             A string
                                                                           An integer
                                                                           assignment
```

Here, name variables, respectively. This produces the following result – 100, 1000.0 and "John" are the values assigned ç counter, miles, and

```
John
                   100
         1000.0
```

### Multiple Assignment

Python allows you to assign a single value to several variables simultaneously

For example-

to the same memory location. You can also assign multiple objects to multiple variables. Here, an integer object is created with the value 1, and all the three variables are assigned

For example-

```
a, b, c = 1, 2, "john"
```

respectively, and one string object with the value "john" is assigned to the variable c. Here, two integer objects with values 1 and 2 are assigned to the variables a and Б

# Standard Data Types

as a numeric value and his or her address is stored as alphanumeric characters. Python and the storage method for each of them. has various standard data types that are used to define the operations possible on them The data stored in memory can be of many types. For example, a person's age is stored

Python has five standard data types-

- Numbers
- String
- List
- Tuple
- Dictionary

## Python Numbers

Number data types store numeric values. Number objects are created when you assign a value to them. For example-

```
Ь
10
```

syntax of the You can also delete the reference del statement is q a number object by using the del statement. The

```
del var1[,var2[,var3[....,varN]]]]]
```

You can delete a single object or multiple objects by using the del statement

For example-

```
del var_a, var_b
```

Python supports three different numerical types –

- int (signed integers)
- float (floating point real values)
- complex (complex numbers)

number type as long. All integers in Python 3 are represented as long integers. Hence, there is no separate

## Examples

Here are some examples of numbers-

4.53e-7j	70.2-E12	0x69
3e+26J	-32.54e100	-0x260
6545+0J	-90.	-0490
.876j	32.3+e18	080
9.322e-36j	-21.9	-786
45.j	15.20	100
3.14j	0.0	10
complex	float	int

A complex number consists of an ordered pair of real floating-point numbers denoted by x + yj, where x and y are real numbers and y is the imaginary unit.

## **Python Strings**

Strings in Python are identified as a contiguous set of characters represented in the quotation marks. Python allows either pair of single or double quotes. Subsets of strings can be taken using the slice operator ([ ] and [:] ) with indexes starting at 0 in the beginning of the string and working their way from -1 to the end.

operator. For example-The plus (+) sign is the string concatenation operator and the asterisk (\*) is the repetition

```
print
                                                                                                                         print
                                                                                                                                                                      #!/usr/bin/python3
  print (str + "TEST") # Prints
                                                 print (str[2:])
                                                                        print (str[2:5])
                                                                                                 print (str[0])
                                                                                                                         (str)
                        (str * 2)
                                                                                                                                                 'Hello World!'
                          #
                                                  #
                                                                          #
                                                                                                   #
                                                 Prints string starting from 3rd character
                                                                         Prints characters starting from 3rd to 5th
                                                                                                  Prints first character of the string
                          Prints
                                                                                                                        Prints complete string
concatenated string
                        string two times
```

This will produce the following result-

```
Hello
                                                           110
Hello World!TEST
                   Hello World!Hello World!
                                         llo World!
                                                                                                   World!
```

## Python Lists

separated by commas and enclosed within square brackets ([]). To some extent, lists are similar to arrays in C. One of the differences between them is that all the items belonging to a list can be of different data type. Lists are the most versatile of Python's compound data types. A list contains items

The values stored in a list can be accessed using the slice operator ( $[\ ]$  and [:]) with indexes starting at 0 in the beginning of the list and working their way to end -1. The plus (+) sign is the list concatenation operator, and the asterisk (\*) is the repetition operator. For example-

```
print
                                        print
                                                           print
                                                                                print
                                                                                                    print (list)
                                                                                                                        tinylist = [123,
                                                                                                                                                                #!/usr/bin/python3
                                        (list[2:])
                                                             (list[1:3])
                                                                               (list[0])
(list + tinylist) # Prints concatenated
                    (tinylist *
                                                                                                                                           [ 'abcd',
                                                                                                                                             786
                                                                                                                       'john']
                     2)
                    # Prints list two times
                                                              #
                                                                                  #
                                     # Prints elements starting from 3rd element
                                                                                                    # Prints complete list
                                                                                                                                             2.23,
                                                          Prints elements starting from 2nd
                                                                                 Prints
                                                                                                                                           'john', 70.2
                                                                                 first element of the list
  lists
                                                              till 3rd
```

This produces the following result-

```
[2.23,
                 [123,
                                                 [786,
['abcd', 786,
                                                                                ['abcd',
                 'john',
                                'john',
                                                                                 786,
2.23,
                123,
                                                                                2.23, 'john',
                                  70.20000000000000003]
                 'john']
'john',
                                                                                  70.2000000000000003]
70.2000000000000003, 123, 'john']
```

## Python Tuples

A tuple is another sequence data type that is similar to the list. A tuple consists of a number of values separated by commas. Unlike lists, however, tuples are enclosed within parenthesis.

their elements and size can be changed, while tuples are enclosed in parentheses and cannot be updated. Tuples can be thought of as **read-only** lists. For example-The main difference between lists and tuples is- Lists are enclosed in brackets (  $[\ ]\ )$  and 

```
print (tuple[2:])
                                                                                                                                      print (tuple[1:3])
                                                                                                                                                                                     print (tuple[0])
                                                                                                                                                                                                                                print (tuple)
                                                                                                                                                                                                                                                                                                                      tuple = ( 'abcd', 786 , 2.23, 'john', 70.2
print (tuple + tinytuple) # Prints concatenated tuple
                                              print (tinytuple * 2)
                                                                                                                                                                                                                                                                               tinytuple = (123, 'john')
                                                                                                                                                                                                                                                                                                                                                                           #!/usr/bin/python3
                                                # Prints tuple two times
                                                                                           # Prints elements starting from 3rd element
                                                                                                                                        # Prints elements starting from 2nd till 3rd
                                                                                                                                                                                     # Prints first element of the tuple
                                                                                                                                                                                                                                  # Prints complete tuple
```

This produces the following result-

```
(786,
('abcd', 786, 2.23, 'john',
                     (123, 'john', 123, 'john')
                                                                                                             ('abcd', 786,
                                                                   2.23)
                                         'john',
                                                                                                              2.23,
                                             70.200000000000000)
                                                                                                              'john',
                                                                                                               70.20000000000000003)
70.2000000000000003,
123, 'john')
```

not allowed. Similar case is possible with lists -The following code is invalid with tuple, because we attempted to update a tuple, which is

```
list = [ 'abcd', 786 , 2.23, 'john', 70.2
                                                                                                                     tuple = ( 'abcd', 786 , 2.23, 'john', 70.2
                                                                                                                                                                   #!/usr/bin/python3
 list[2] = 1000
                                       tuple[2] = 1000
                                          # Invalid syntax with tuple
# Valid syntax with list
```

## Python Dictionary

arbitrary Python object. Python type, but are usually numbers or strings. Values, on the other hand, can be any hashes found in Perl and consist of key-value pairs. A dictionary key can be almost any Python's dictionaries are kind of hash-table type. They work like associative arrays or

using square braces ([]). For example-Dictionaries are enclosed by curly braces ( $\{\ \}$ ) and values can be assigned and accessed

```
print (tinydict.values()) # Prints
                                                            print (tinydict)
                                                                                         print (dict[2])
                                                                                                                          print (dict['one'])
                                                                                                                                                      tinydict = {'name':
                                                                                                                                                                                      dict[2]
                                                                                                                                                                                                                     dict['one'] = "This
                                                                                                                                                                                                                                                                               #!/usr/bin/python3
                              (tinydict.keys())
                                                                                                                                                                                      = "This is two"
                                                                                                                                                                                                                  is one"
                                                                                                                                                    'john','code':6734, 'dept': 'sales'}
                            # Prints all the keys
                                                                                            # Prints value for 2 key
                                                                                                                           # Prints value for 'one' key
                                                             # Prints complete dictionary
all the values
```

This produces the following result-

```
['dept',
                                         {'dept': 'sales',
                                                               This is two
['sales', 6734, 'john']
                                                                                    one
                      'code',
                      'name']
                                         'code': 6734, 'name': 'john'}
```

elements are "out of order"; they are simply unordered. Dictionaries have no concept of order among the elements. It is incorrect to say that the

# **Data Type Conversion**

between types, you simply use the type-name as a function. Sometimes, you may need to perform conversions between the built-in types. To convert

These functions return a new object representing the converted value. There are several built-in functions to perform conversion from one data type to another.

Function	Description
int(x [,base])	Converts $\boldsymbol{x}$ to an integer. The base specifies the base if $\boldsymbol{x}$ is a string.
float(x)	Converts $x$ to a floating-point number.
complex(real [,imag])	Creates a complex number.

	יייים אורי הייב אירי בי הייב אמת בכוווימי סבווויאי
hev(v) Converts an integer to	a hevadecimal string
ord(x) Converts a single char	Converts a single character to its integer value.
unichr(x) Converts an integer to a Unicode character.	o a Unicode character.
chr(x) Converts an integer to a character.	o a character.
frozenset(s) Converts s to a frozen set.	ı set.
dict(d) Creates a dictionary. d	Creates a dictionary. d must be a sequence of (key,value) tuples.
set(s) Converts s to a set.	
list(s) Converts s to a list.	
tuple(s) Converts s to a tuple.	
eval(str) Evaluates a string and returns an object.	d returns an object.
repr(x) Converts object x to an expression string.	าก expression string.
str(x) Converts object x to a	Converts object ${\sf x}$ to a string representation.

# 6. Python 3 — Basic Operators

Operators are the constructs, which can manipulate the value of operands. Consider the expression 4+5=9. Here, 4 and 5 are called operands and + is called the operator.

## Types of Operator

Python language supports the following types of operators-

- Arithmetic Operators
- Comparison (Relational) Operators
- Assignment Operators
- Logical Operators
- Bitwise Operators
- Membership Operators
- Identity Operators

Let us have a look at all the operators one by one.

# Python Arithmetic Operators

Assume variable  ${f a}$  holds the value 10 and variable  ${f b}$  holds the value 21, then-

Operator	Description	Example
+ Addition	Adds values on either side of the operator.	a + b = 31
- Subtraction	Subtracts right hand operand from left hand operand.	a – b = -11
* Multiplication	Multiplies values on either side of the operator	a * b = 210
/ Division	Divides left hand operand by right hand operand	b/a=2.1
% Modulus	Divides left hand operand by right hand operand and returns remainder	b % a = 1
** Exponent	Performs exponential (power) calculation on operators	a**b =10 to the power 20

Floor Division - The division of operands where $9//2 = 4$ and the result is the quotient in which the digits $9.0//2.0 = 4.0$ after the decimal point are removed.
Floor Division - The division of operands where $9//2 = 4$ and the result is the quotient in which the digits $9.0//2.0 = 4.0$ after the decimal point are removed.
9//2 = 4 and 9.0//2.0 = 4.0
4 and = 4.0

#### Example

Assume variable a holds 10 and variable b holds 20, then-

```
a = 21
print ("Line 7
                                            print ("Line 6
                                                                                        print ("Line
                                                                                                                                             print ("Line 3
                                                                                                                                                                        print ("Line 2
                                                                                                                                                                                                   print ("Line
                                                                                                                                                                                                                                               #!/usr/bin/python3

# Python Comparison Operators

These operators compare the values on either side of them and decide the relation among them. They are also called Relational operators.

Assume variable a holds the value 10 and variable b holds the value 20, then-

^	>= If	ol It	o) If	i= If	== If	Operator
If the value of left operand is less than or equal to the value of right operand, then condition becomes true.	If the value of left operand is greater than or equal to the value of right operand, then condition becomes true.	If the value of left operand is less than the value of right operand, then condition becomes true.	If the value of left operand is greater than the value of right operand, then condition becomes true.	If values of two operands are not equal, then condition becomes true.	If the values of two operands are equal, then the condition becomes true.	Description
(a <= b) is true.	(a >= b) is not true.	(a < b) is true.	(a > b) is not true.	(a!= b) is true.	(a == b) is not true.	Example

#### Example

Assume variable a holds 10 and variable b holds 20, then-

```
a = 21
b = 10
if ( a == b ):
    print ("Line :
else:
                                                #!/usr/bin/python3
            а
          İS
          equal to b")
```

```
if ( a > b ):
    print ("Line '
                                                                                                                                                                                                                                     if ( a < b ):
    print ("Line</pre>
                                                                                                                                                                                                                                                                                                                  ť

# Python Assignment Operators

Assume variable a holds 10 and variable b holds 20, then-

Operator	Description	Example
11	Assigns values from right side operands to   c = a + b assigns   left side operand   value of a + b into c	c = a + b assigns value of a + b into c
+= Add AND	It adds right operand to the left operand $c += a$ is equivalent and assign the result to left operand $c += a$ is equivalent	c += a is equivalent to $c = c + a$

c//= a is equivalent to $c = c//a$	It performs floor division on operators and assign value to the left operand	//= Floor Division
c **= a is equivalent to c = c ** a	Performs exponential (power) calculation on operators and assign value to the left operand	**= Exponent AND
c % = a is equivalent to $c = c %$ a	It takes modulus using two operands and assign the result to left operand	%= Modulus AND
<pre>c /= a is equivalent to c = c / ac /= a is equivalent to c = c / a</pre>	It divides left operand with the right operand and assign the result to left operand	/= Divide AND
c *= a is equivalent to c = c * a	It multiplies right operand with the left operand and assign the result to left operand	*= Multiply AND
c -= a is equivalent to c = c - a	It subtracts right operand from the left operand and assign the result to left operand	-= Subtract AND

### Example

Assume variable a holds 10 and variable b holds 20, then-

```
Ь
print ("Line 3
                             print ("Line 2
                                                         print ("Line 1 - Value of c
                                                                                       0
                                                                                                                           #!/usr/bin/python3
                                                                                                = 10

# Python Bitwise Operators

Bitwise operator works on bits and performs bit-by-bit operation. Assume if a b=13; Now in binary format they will be as follows-Ш 60; and

```
a&b = 0000 1100

a|b = 0011 1101

a^b = 0011 0001

~a = 1100 0011
```

= 0000 1101

0011 1100

number. Pyhton's built-in function bin() can be used to obtain binary representation of an integer

The following Bitwise operators are supported by Python language-

Operator	Description	Example
& Binary AND	Operator copies a bit to the result, if it exists in both operands	(a & b) (means 0000 1100)
Binary OR	It copies a bit, if it exists in either operand.	(a   b) = 61 (means 0011 1101)
^ Binary XOR	It copies the bit, if it is set in one operand but not both.	(a ^ b) = 49 (means 0011 0001)
~ Binary Ones Complement	It is unary and has the effect of 'flipping' bits.	(~a) = -61 (means 1100 0011 in 2's complement form due to a signed binary number.
<< Binary Left Shift	The left operand's value is moved left by the number of bits specified by the right operand.	a << = 240 (means 1111 0000)
>> Binary Right Shift	The left operand's value is moved right by the number of bits specified by the right operand.	a >> = 15 (means 0000 1111)

#### Example

```
a = 60
print ("result of OR is ", c,':',bin(c))
                                                                         print ("result of AND is ", c,':',bin(c))
                                                                                                                                                         \circ
                                                                                                                                                                              print ('a=',a,':',bin(a),'b=',b,':',bin(b))
                                                                                                                                                                                                           b = 13
                                                                                                                                                                                                                                                                                     #!/usr/bin/python3

```

# Python Logical Operators

The following logical operators are supported by Python language. Assume variable a holds True and variable b holds False then-

Operator	Description	Example
and Logical AND	If both the operands are true then condition becomes true.	(a and b) is False.
or Logical OR	If any of the two operands are non-zero then condition becomes true.	(a or b) is True.
not Logical NOT	Used to reverse the logical state of its operand.	Not(a and b) is True.

# Python Membership Operators

Python's membership operators test for membership in a sequence, such as strings, lists, or tuples. There are two membership operators as explained below-

Operator	Description	Example
in	Evaluates to true, if it finds a variable   x in y, here in results in in the specified sequence and false otherwise.   x in y, here in results in sequence y.	x in y, here in results in a 1 if x is a member of sequence y.
not in	Evaluates to true, if it does not find a x not in y, here not in variable in the specified sequence and false otherwise. x not in y, here not in results in a 1 if x is not a member of sequence y.	x not in y, here not in results in a 1 if x is not a member of sequence y.

#### Example

```
print ("Line
              else:
                                                     c=b/a
                                                                                                                      if
                                                                                                                                                              else:
                                                                                                                                                                                        if
                                                                                                                                                                                                                                                                      #!/usr/bin/python3

# Python Identity Operators

Identity operators compare the memory locations of two objects. There are two Identity operators as explained below:

Operator	Description	Example
ïs	Evaluates to true if the variables on $x$ is $y$ , here is results either side of the operator point to the same object and false otherwise. $x$ is $y$ , here is results in $y$ i	x is $y$ , here is results in 1 if $id(x)$ equals $id(y)$ .
is not	Evaluates to false if the variables on $x$ is not $y$ , here is either side of the operator point to the same object and true otherwise. $x$ is not equal to id( $y$ ).	x is not $y$ , here is not results in 1 if id( $x$ ) is not equal to id( $y$ ).

### Example

```
print ('Line 1', 'a=',a,':',id(a), 'b=',b,':',id(b))
                                                   냒
                                                                                                                                        냙
                                                                                                                                                                                                                                           #!/usr/bin/python3
print ("Line
                                  print ("Line 3
                                                  (id(a) == id(b)
                                                                                   print ("Line
                                                                                                                    print ("Line 2
                                                                                                                                       ( a is b ):

```

# Python Operators Precedence

The following table lists all the operators from highest precedence to the lowest.

Operator	Description
*	Exponentiation (raise to the power)
2 + -	Ccomplement, unary plus and minus (method names for the last two are +@ and -@)
* / % //	Multiply, divide, modulo and floor division
+ -	Addition and subtraction
>> <<	Right and left bitwise shift
&	Bitwise 'AND'
<u>&gt;</u>	Bitwise exclusive `OR' and regular `OR'
<= < > >=	Comparison operators
\    -  -	Equality operators

Operator precedence affects the evaluation of an an expression.

For example, x = 7 + 3 \* 2; here, x is assigned 13, not 20 because the operator \* has higher precedence than +, so it first multiplies 3\*2 and then is added to 7.

the lowest appear at the bottom. Here, the operators with the highest precedence appear at the top of the table, those with

## Example

```
print ("Value of a + (b
                                                                                                                                                                        print ("Value of ((a + b) * c) / d is ", e)
                                                                                                                                                                                                                                                              print ("Value of (a + b) * c / d is ",
                                                                                                                                                                                                                                                                                                                       print ("a:%d b:%d c:%d d:%d" % (a,b,c,d ))
                                                                                        print ("Value of (a + b) * (c / d) is ",
                                                                                                                                                                                                                                                                                         e = (a + b) * c / d
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            #!/usr/bin/python3
                                                                                                                                                                                                                                                                                                                                                                                    ||

                                                                                                                                                                                                                                                                                          #( 30 * 15 ) / 5
                                                                                                               # (30) * (15/5)
                                                                                                                                                                                                       # (30 * 15 ) / 5
                                                                                        е)
```

When you execute the above program, it produces the following result-

```
Value of (a + b) *
              a:20 b:10 c:15 d:5
0
\
d is
 90.0
```

```
Value of ((a + b) * c) / d is 90.0

Value of (a + b) * (c / d) is 90.0

Value of a + (b * c) / d is 50.0
```

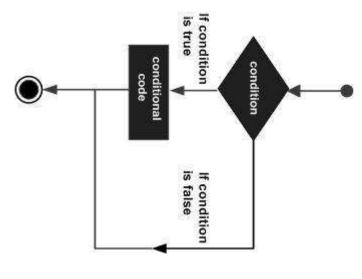

# 7. Python 3 — Decision Making

program and specified actions taken according to the conditions. Decision-making is the anticipation of conditions occurring during the execution of a

the outcome is TRUE or FALSE otherwise. Decision structures evaluate multiple expressions, which produce TRUE or FALSE as the outcome. You need to determine which action to take and which statements to execute if

programming languages-Following is the general form of a typical decision making structure found in most of the

Python programming language assumes any **non-zero** and **non-null** values as TRUE, and any **zero** or **null values** as FALSE value.

statements Python programming language provides the following types decision-making

Statement	Description
if statements	An if statement consists of a Boolean expression followed by one or more statements.
ifelse statements	An if statement can be followed by an optional else statement, which executes when the boolean expression is FALSE.

וופטנפט וו טנמנפווופוונט	posted if statements
another if or else if statement(s).	You can use one if or else if statement inside

Let us go through each decision-making statement quickly.

## IF Statement

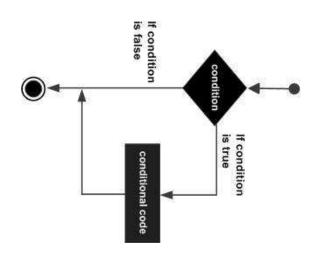

The IF statement is similar to that of other languages. The **if** statement contains a logical expression using which the data is compared and a decision is made based on the result of the comparison.

#### Syntax

```
if expression:
statement(s)
```

statement is executed. In Python, statements in a block are uniformly indented after the If the boolean expression evaluates to TRUE, then the block of statement(s) inside the if end of block is executed. : symbol. If boolean expression evaluates to FALSE, then the first set of code after the

## Flow Diagram

#### Example

```
ť
                                                             var1 = 100
                                                                               #!/usr/bin/python3
                                          var1:
                   print ("1 -
print (var1)
                  Got a true expression value")
```

14

```
print ("Good bye!")
                                                                         var2
                                                        if var2:
                                     print
                   print (var2)
                                                                         П
                                                                         0
                                    ("2 - Got a true expression value")
```

When the above code is executed, it produces the following result

```
100
Good bye!
                            Got
                            a
                           true expression value
```

# IF...ELIF...ELSE Statements

An **else** statement can be combined with an **if** statement. An **else** statement contains a block of code that executes if the conditional expression in the if statement resolves to 0 or a FALSE value.

The else statement is an optional statement and there one **else** statement following **if**. could be at the most only

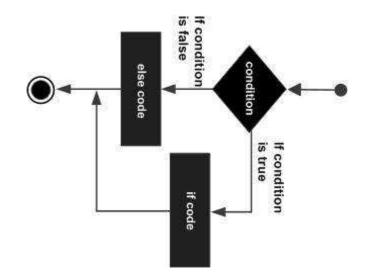

#### Syntax

The syntax of the if...else statement is-

```
else:
                                            if
                                            expression:
                            statement(s)
statement(s)
```

## Flow Diagram

#### Example

```
print ("Net payable:",amount-discount)
                                                                                                                                        else:
                                                                                                                                                                                                                                                                       amount=int(input("Enter amount: "))
                                                                                                                                                                                                                                                                                                          #!/usr/bin/python3
                                                                                                                                                                                                                                          if amount<1000:
                                                                print ("Discount", discount)
                                                                                                     discount=amount*0.10
                                                                                                                                                                    print ("Discount", discount)
                                                                                                                                                                                                         discount=amount*0.05
```

In the above example, discount is calculated on the input amount. Rate of discount is 5%, if the amount is less than 1000, and 10% if it is above 10000. When the above code is executed, it produces the following result-

```
Net payable: 570.0
                                                                     Discount 30.0
Discount 120.0
                       Enter amount: 1200
                                                                                            Enter amount:
                                                                                             600
```

```
payable:
 1080.0
```

## The elif Statement

The **elif** statement allows you to check multiple expressions for TRUE and execute a block of code as soon as one of the conditions evaluates to TRUE.

following an if. Similar to the **else**, the **elif** statement is optional. However, unlike **else**, for which there can be at the most one statement, there can be an arbitrary number of **elif** statements

#### Syntax

```
elif expression2:
                                                                    elif expression3:
                                                                                                                                                               expression1:
                                            statement(s)
statement(s)
                                                                                          statement(s)
                                                                                                                                         statement(s)
```

use if..elif...statements to simulate switch case as follows-Core Python does not provide switch or case statements as in other languages, but we can

#### Example

```
print
                                                                                               else:
                                                                                                                                                                                                                                                                                        ť
                                                                                                                                                                                                                                                                                                                                                                                  #!/usr/bin/python3
                                                                                                                                                                                         elif amount<5000:
                                                                                                                                                                                                                                                                                                                                                    amount=int(input("Enter amount: "))
                                                                                                                                                                                                                                                                                       amount<1000:
                              print ("Discount", discount)
                                                               discount=amount*0.15
                                                                                                                           print ("Discount", discount)
                                                                                                                                                                                                                       print ("Discount", discount)
                                                                                                                                                          discount=amount*0.10
                                                                                                                                                                                                                                                     discount=amount*0.05
 ("Net payable:",amount-discount)
```

When the above code is executed, it produces the following result-

```
Net payable: 5100.0
                                                                                                          Net payable: 2700.0
                             Discount 900.0
                                                                                                                                       Discount 300.0
                                                                                                                                                                                                                       Net payable: 570.0

# **Nested IF Statements**

There may be a situation when you want to check for another condition after a condition resolves to true. In such a situation, you can use the nested **if** construct.

if...elif...else construct. a nested if construct, you can have an if...elif...else construct inside another

#### Syntax

The syntax of the nested if ... elif ... else construct may be-

```
if
                     else:
                                                         elif expression4:
                                                                                                                                                                                                                     expression1:
                                     statement(s)
statement(s)
                                                                                                                                       elif expression3:
                                                                                                                                                                              if expression2:
                                                                                                                                                                                                 statement(s)
                                                                                                                    statement(s)
                                                                             statement(s)
                                                                                                                                                          statement(s)
```

#### Example

```
num=int(input("enter
                       # !/usr/bin/python3
number"))
```

```
else:
                                                                                                                                                                                                                                                           if
                                                                                                                                                                                                                                                         num%2==0:
                                                                                                                                                                                                                               if num%3==0:
                                                                                    if num%3==0:
                                                       print ("divisible by 3 not divisible by 2")
                                                                                                                                                                                                  print ("Divisible by 3 and 2")
  print
                                                                                                                                           print ("divisible by 2 not divisible by 3")
("not Divisible
by 2 not divisible by 3")
```

When the above code is executed, it produces the following result-

```
not Divisible by 2 not divisible by
                                   enter number5
                                                                                                       Divisible by 3 and 2
                                                                                                                                                                                                                                                                                                                       divisible by 2 not divisible by 3
                                                                                                                                           enter number12
                                                                                                                                                                                                               divisible by 3 not divisible by 2
                                                                                                                                                                                                                                                 enter number15
                                                                                                                                                                                                                                                                                                                                                         number8
```

# Single Statement Suites

header statement. If the suite of an **if** clause consists only of a single line, it may go on the same line as the

Here is an example of a one-line if clause-

```
print ("Good bye!")
                                                                            #!/usr/bin/python3
                            if ( var
                        == 100 ) : print ("Value of expression is
                            100")
```

When the above code is executed, it produces the following result-

```
Good bye!
                              Value of expression is 100
```

# 8. Python 3 — Loops

to execute a block of code several number of times. In general, statements are executed sequentially- The first statement in a function is executed first, followed by the second, and so on. There may be a situation when you need

execution paths. Programming languages provide various control structures that allow more complicated

The following diagram illustrates a loop statement. A loop statement allows us to execute a statement or group of statements multiple times.

Python programming language provides the following types of loops to handle looping requirements.

Loop Type	Description
while loop	Repeats a statement or group of statements while a given condition is TRUE. It tests the condition before executing the loop body.
for loop	Executes a sequence of statements multiple times and abbreviates the code that manages the loop variable.

# while Loop Statements

A **while** loop statement in Python programming language repeatedly executes statement as long as a given condition is true. a target

#### Syntax

The syntax of a while loop in Python programming language is-

```
while expression:
statement(s)
```

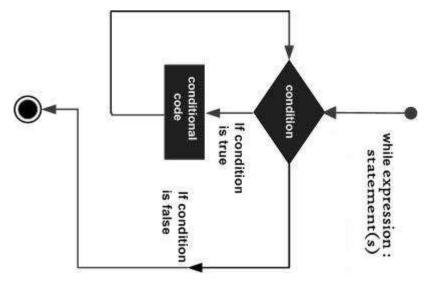

indent. The **condition** may be any expression, and true is any non-zero value. The loop iterates while the condition is true. statement(s) may be a single statement or a block of statements with uniform

following the loop. When the condition becomes false, program control passes to the line immediately

programming construct are considered to be part of a single block of code. Python uses indentation as its method of grouping statements. In Python, all the statements indented by the same number of character spaces after a

## Flow Diagram

Here, a key point of the while loop is that the loop might not ever run. When the condition is tested and the result is false, the loop body will be skipped and the first statement after the while loop will be executed.

### Example

```
while
print ("Good bye!")
                                                                                                                                 #!/usr/bin/python3
                                                                                               count =
                                                       print ('The count is:', count)
                                       count = count + 1
                                                                         (count <
                                                                                               0
                                                                         9):
```

When the above code is executed, it produces the following result-

```
The
        The
               The
                       The
                               The
        count
                               count
               count
count
                       count is: 1
15:
        is:
                               is:
               is:
        ω
4
```

```
The
                                   The
Good bye!
                          The count
                count
         count
                                  count
                 is:
         is:
                          is:
                                   is:
                          6
                 7
```

The block here, consisting of the print and increment statements, is executed repeatedly until count is no longer less than 9. With each iteration, the current value of the index count is displayed and then increased by 1.

## The Infinite Loop

when using while loops because of the possibility that this condition never resolves to a FALSE value. This results in a loop that never ends. Such a loop is called an infinite loop. A loop becomes infinite loop if a condition never becomes FALSE. You must be cautious

run continuously so that client programs can communicate with it as and when required. An infinite loop might be useful in client/server programming where the server needs to

```
while var == 1
                                                                                                                           var =
                                                                                                                                                       #!/usr/bin/python3
                                                            num = int(input("Enter a number
                              print ("You entered: ", num)
("Good bye!")
                                                                                            # This constructs an infinite loop
                                                             :":
```

When the above code is executed, it produces the following result-

```
KeyboardInterrupt
                                                              Enter a number
                                                                               You entered:
                                                                                                     Enter a number

                    a number
                                         Τ'n
```

program. The above example goes in an infinite loop and you need to use CTRL+C to exit the

# **Using else Statement with Loops**

Python supports having an else statement associated with a loop statement

- If the else statement is used with a for loop, the else statement is executed when the loop has exhausted iterating the list.
- when the condition becomes false. If the **else** statement is used with a **while** loop, the **else** statement is executed

The following example illustrates the combination of an else statement that prints a number as long as it is less than 5, othe gets executed. otherwise the else statement statement with a while

```
else:
                                                       while
                                                                                #!/usr/bin/python3
                                                                    count =
print
                                        print (count,
                            count = count +
                                                      count < 5:
                                                                     0
(count,
  =
                                            =
                            \vdash
                                         is
 is
 not
                                        less than 5")
 less
than 5")
```

When the above code S. executed, it produces the following result-

```
4
                           \sim
         İS
                           15
                                    is
is
                  İS
                                             ÌS
                  less
                           less
                                    less
         less than
                                             Less
not less than 5
                  than
                           than
                                    than
                                            than
                                    Ф
```

# **Single Statement Suites**

it may be placed on the same line as the while header. Similar to the **if** statement syntax, if your **while** clause consists only of a single statement,

Here is the syntax and example of a one-line while clause-

```
print ("Good bye!")
                                                                         #!/usr/bin/python3
                        (flag): print ('Given flag
                         is
                         really true!')
```

The above example goes into an infinite loop and you need to press CTRL+C keys to exit.

# for Loop Statements

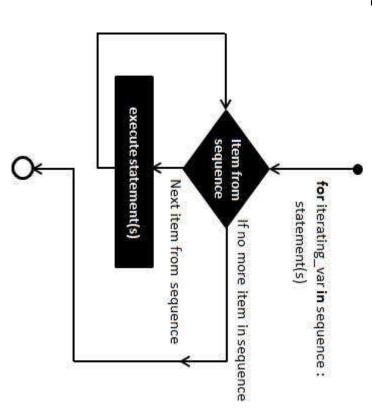

The for statement in Python has the ability to iterate over the items of any sequence, such as a list or a string.

#### Syntax

```
for iterating_var
statements(s)
                    ij.
                    sequence:
```

sequence is assigned to the iterating variable *iterating\_var*. Next, the statements block is executed. Each item in the list is assigned to *iterating\_var*, and the statement(s) block is executed until the entire sequence is exhausted. If a sequence contains an expression list, it is evaluated first. Then, the first item in the

## Flow Diagram

## The range() function

The built-in function range() is the right function to iterate over a sequence of numbers. It generates an iterator of arithmetic progressions.

```
>>> range(5)
[0, 1, 2, 3, 4]
                                      range(0, 5)
                 list(range(5))
```

range() generates an iterator to progress integers starting with 0 upto n-1. To obtain a list object of the sequence, it is typecasted to list(). Now this list can be iterated using the for statement. To obtain a

```
for var in list(range(5)):
print (var)
```

This will produce the following output.

```
ω
  2
         0
```

#### Example

```
print()
print ("Good bye!")
                                                                                                                                                                                                           #!/usr/bin/python3
                                                                               for fruit in fruits:
                                                                                                       fruits =
                                                                                                                                                                                   for letter in 'Python':
                                                   print ('Current fruit :', fruit)
                                                                                                                                                      print ('Current Letter :', letter)
                                                                                                  ['banana', 'apple',
                                                                                                                                                                                   #
                                                                            traversal of List sequence
                                                                                                     'mango']
                                                                                                                                                                                  traversal of
                                                                                                                                                                                    മ
                                                                                                                                                                                  string sequence
```

When the above code <u>v</u>. executed, it produces the following result

```

                                                                                                                Letter
                           apple
                                          banana
                                                                                   0
                                                                                                 ᠴ
```

# Iterating by Sequence Index

itself. Following is a simple example-An alternative way of iterating through each item is by index offset into the sequence

```
for index in range(len(fruits)):
                                                                                  fruits = ['banana',
print ("Good bye!")
                                                                                                               #!/usr/bin/python3
                        print ('Current fruit :', fruits[index])
                                                                                  'apple',
                                                                                   'mango']
```

When the above code is executed, it produces the following result-

```
Current
Good bye!
             Current fruit
                                         Current
                           fruit
                                         fruit
             mango
                           apple
                                         banana
```

of elements in the tuple as well as the range() built-in function to give us the actual sequence to iterate over. Here, we took the assistance of the len() built-in function, which provides the total number

# **Using else Statement with Loops**

Python supports having an else statement associated with a loop statement.

- loops terminates normally (and not by encountering break statement). If the else statement is used with a for loop, the else block is executed only if for
- when the condition becomes false. If the **else** statement is used with a **while** loop, the **else** statement is executed

statement that searches for even number in given list. The following example illustrates the combination of an else statement with മ for

```
numbers=[11,33,55,39,55,75,37,21,23,41,13]
                                                                                                                                                                                       #!/usr/bin/python3
                                                                                                                                    for num in numbers:
print ('the
                                                                                                          if num%2==0:
                                                       break
                                                                               print ('the list contains
    list
    doesnot
   contain even number')
                                                                                  an even number')
```

When the above code is executed, it produces the following result-

```
the list does not
contain even number
```

## **Nested loops**

Python programming language allows Python programming language allows the use of one loop inside following section shows a few examples to illustrate the concept. another loop. The

#### Syntax

```
for iterating_var
statements(s)
                                       for iterating_var
                    statements(s)
                                                              Ħ.
                                        in sequence:
                                                             sequence:
```

follows-The syntax for a nested while loop statement in Python programming language <u>s</u>. as

```
while expression:
                                                 while expression:
statement(s)
                         statement(s)
```

loop. For example a for loop can be inside a while loop or vice versa. A final note on loop nesting is that you can put any type of loop inside any other type of

#### Example

The following program uses a nested-for loop to display multiplication tables from 1-10.

```
#!/usr/bin/python3
import sys
```

```
for
                                                                         i in range(1,11):
print()
                                                      for j in range(1,11):
                                     k=i*j
                print (k, end=' ')
```

newline. Hence, the numbers will appear in one row. The print() function inner loop has end=' ' which appends а space instead 앜 default

Last print() will be executed at the end of inner for loop.

When the above code is executed, it produces the following result –

```
9 8
                                 400
10
                                                      10 15
         16 24 32 40 48 56 64 72 80
18 27 36 45 54 63 72 81 90
                                 14 21 28 35 42 49 56 63 70
                                            12 18 24 30
                                                                8 12 16 20 24 28 32 36 40
20
                                                                             9 12 15 18 21 24 27 30
                                                                                    3 4 5 6 7 8 9 10
6 8 10 12 14 16 18 20
30
                                                       20 25
40 50 60
                                            36
                                                       30
                                            42 48 54 60
                                                      35 40 45 50
70 80 90 100
```

## **Loop Control Statements**

The Loop control statements change the execution from its normal sequence. When the execution leaves a scope, all automatic objects that were created in that scope are destroyed.

Python supports the following control statements.

Control Statement	Description
break statement	Terminates the loop statement and transfers execution to the statement immediately following the loop.
continue statement	Causes the loop to skip the remainder of its body and immediately retest its condition prior to reiterating.

not want any command or code to execute.	
statement is required syntactically but you do	
The pass statement in Python is used when a	pass statement

Let us go through the loop control statements briefly.

## break statement

abandoning the loop, execution at the next statement is resumed, just like the traditional break statement in C.

The most common use of break is when some external condition is triggered requiring a hasty exit from a loop. The **break** statement can be used in both while and for loops.

If you are using nested loops, the break statement stops the execution of the innermost loop and starts executing the next line of the code after the block.

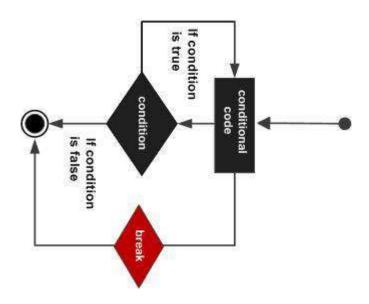

#### Syntax

The syntax for a **break** statement in Python is as follows-

break

## Flow Diagram

#### Example

```
print ("Good bye!")
                                                                                                                                     while var >
                                                                                                                                                             var =
                                                                                                                                                                                                                                                                                                 #!/usr/bin/python3
                                                                                                                                                                                                                                                                            for letter in 'Python':
                                                                                                              print ('Current variable value :', var)
                                                                                                                                                                                                        print ('Current Letter :', letter)
                                                                                                                                                                                                                                                    if letter == 'h':
                                                                   if var == 5:
                                                                                          var = var -1
                                              break
                                                                                                                                                              10
                                                                                                                                         0
                                                                                                                                                              #
                                                                                                                                                                                                                                                                            # First Example
                                                                                                                                                             Second Example
```

When the above code is executed, it produces the following result-

```
Current
Current Letter
                          Current Letter
            Letter
                           ₽
ф
           \checkmark
```

```
Good bye!
                   Current variable value :
                                    Current variable value
                                                       Current variable
                                                                         Current variable value
                                                                                           Current
                                                                                           variable
                                                                                           value
                                                       value
                   6
                                                      \infty
                                       7
                                                                                          10
```

User inputs a number, which is searched in the list. If it is found, then the loop terminates with the 'found' message. The following program demonstrates the use of break in a for loop iterating over a list.

```
else:
                                                                                                                                                                                       numbers=[11,33,55,39,55,75,37,21,23,41,13]
                                                                                                                                                                                                                      no=int(input('any number: '))
                                                                                                                                                                                                                                                      #!/usr/bin/python3
                                                                                                                                                           for num in numbers:
print ('number not found in
                                                                                                                           if num==no:
                                                                break
                                                                                            print ('number found in list')
  list')
```

The above program will produce the following output-

```
number found in list
number not found in list
                       any number:
                                                                       any number: 33
                         ъ
```

## continue Statement

When encountered, the loop starts next iteration without executing the statements in the current iteration. The continue statement in Python returns the control to the beginning of the current loop. remaining

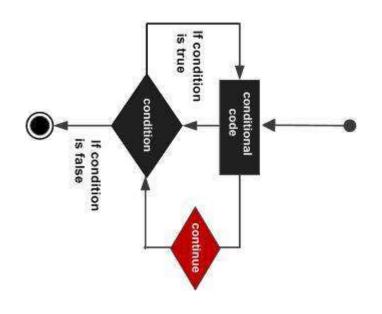

The **continue** statement can be used in both while and for loops

#### Syntax

continue

## Flow Diagram

#### Example

```
print ("Good bye!")
                                                                                                                                                                                                                                                            #!/usr/bin/python3
                                                                                                 while var > 0:
                                                                                                                      var =
                                                                                                                                                                                                                      for letter in 'Python':
                  print ('Current variable value :', var)
                                                                                                                                                                                                   if letter ==
                                                                             var = var -1
                                                                                                                                                          print ('Current Letter :',
                                                            if var == 5:
                                                                                                                      10
                                        continue
                                                                                                                                                                                continue
                                                                                                                                                                                                    h':
                                                                                                                                                                                                                       #
                                                                                                                       #
                                                                                                                    Second Example
                                                                                                                                                             letter)
                                                                                                                                                                                                                      First Example
```

When the above code is executed, it produces the following result-

```
Current
Letter
P
```

```
Good bye!

## pass Statement

or code to execute. It is used when a statement is required syntactically but you do not want any command

been written yet i.e. in stubs). pass statement is also useful in places where your code will eventually go, but has not The **pass** statement is a null operation; nothing happens when it executes. The

#### Syntax

```
pass
```

#### Example

```
print ("Good bye!")
                                                                                                                                                                           for
                                                                                                                                                                                                                                  #!/usr/bin/python3
                                                          print ('Current Letter :', letter)
                                                                                                                                                if letter == 'h':
                                                                                                                                                                         letter in 'Python':
                                                                                   print ('This is pass block')
                                                                                                                  pass
```

When the above code is executed, it produces the following result-

```
Good bye!
             Current Letter
                          Current Letter

## Iterator and Generator

implements two methods, iter() and next(). Iterator is an object, which allows a programmer to traverse through all the elements of collection, regardless of its specific implementation. 'n Python, an iterator object

String, List or Tuple objects can be used to create an Iterator.

```
it =
                                                                                                                                                                                                                                                                        !usr/bin/python3
                                                                                                                                      while True:
                                                                                                                                                                       or using next() function
                                                                                                                                                                                                                                             for x in it:
                                                                                                                                                                                                                                                                                                           Iterator object can be traversed using regular for statement
                                                                                                                                                                                                                                                                                                                                                print (next(it)) #prints next available element in

 for this
                                                                                                                                                                                                                                                                                                                                                iterator
```

A generator is a function that produces or yields a sequence of values using yield method.

execution of the function. When the next() method is called for the first time, the function starts executing, until it reaches the yield statement, which returns the yielded value. The When a generator function is called, it returns a generator object without even beginning from previous value. yield keeps track i.e. remembers the last execution and the second next() call continues

numbers The following example defines a generator, which generates an iterator for all the Fibonacci

```
!usr/bin/python3
```

```
while True:
                                                                                                                                                                                                                                                                                                                           def fibonacci(n): #generator function
                                                                                                                                                                                                                                                                                                                                                   import sys

                                                                                                                                                             counter += 1
                                                                                                                                                                                    a, b = b, a + b
                                                                                                                                                                                                                                  return
```

# Python 3 – Numbers

Number data types store numeric values. They are immutable data types changing the value of a number data type results in a newly allocated object. This means,

Number objects are created when you assign a value to them. For example

```
var1
var2 = 10
```

syntax of the You can also delete the reference to del statement is മ number object by using the **del** statement. The

```
del var1[,var2[,var3[....,varN]]]]
```

You can delete a single object or multiple objects by using the **del** statement. For example-

```
del var_a, var
```

Python supports different numerical types-

- of unlimited size. Python 2 has two integer types int and long. There is no 'long positive or negative whole numbers with no decimal point. Integers in Python 3 are int (signed integers): They are often called just integers or ints. integer' in Python 3 anymore. They
- parts. Floats may also be in scientific notation, with E or e indicating the power of numbers and are written with a decimal point dividing the integer and the fractional float (floating point real values): Also called floats, they represent real  $= 2.5 \times 10^2 = 250$ ).
- real part of the number is a, and the imaginary part is b. Complex numbers are not **complex (complex numbers)**: are of the form a + bJ, where a and b are floats and J (or j) represents the square root of -1 (which is an imaginary number). The used much in Python programming.

It is possible to represent an integer in hexa-decimal or octal form.

```
2575
                                                                                >>> number
>>> number
                    >>> number=0o37 #Octal
                                                                                                    number
                                                                                                    0xA0F
                                                                                                  #Hexa-decimal
```

31

#### **Examples**

Here are some examples of numbers.

int	float	complex
10	0.0	3.14j
100	15.20	45.j
-786	-21.9	9.322e-36j
080	32.3+e18	.876j
-0490	-90.	6545+0J
-0x260	-32.54e100	3e+26J
0x69	70.2-E12	4.53e-7j

A complex number consists of an ordered pair of real floating-point numbers denoted by a + bj, where a is the real part and b is the imaginary part of the complex number.

## **Number Type Conversion**

Python converts numbers internally in an expression containing mixed types to a common type for evaluation. Sometimes, you need to coerce a number explicitly from one type to another to satisfy the requirements of an operator or function parameter.

- Type int(x) to convert x to a plain integer.
- Type long(x) to convert x to a long integer.
- Type float(x) to convert x to a floating-point number.
- part zero. Type complex(x) to convert x to a complex number with real part x and imaginary
- imaginary part y. x and y are numeric expressions. Type complex(x, y) to convert x and y to a complex number with real part x and

## **Mathematical Functions**

Python includes the following functions that perform mathematical calculations.

•	
Function	Returns ( Description )
abs(x)	The absolute value of $x$ : the (positive) distance between $x$ and zero.
ceil(x)	The ceiling of $x$ : the smallest integer not less than $x$ .
cmp(x, y)	-1 if $x < y$ , 0 if $x == y$ , or 1 if $x > y$ . <b>Deprecated</b> in Python 3; Instead use <b>return</b> ( $x>y$ )-( $x).$
exp(x)	The exponential of x: e <sup>x</sup>
fabs(x)	The absolute value of $x$ .
floor(x)	The floor of $x$ : the largest integer not greater than $x$ .
log(x)	The natural logarithm of $x$ , for $x > 0$ .
log10(x)	The base-10 logarithm of x for $x>0$ .
max(x1, x2,)	The largest of its arguments: the value closest to positive infinity.
min(x1, x2,)	The smallest of its arguments: the value closest to negative infinity.
modf(x)	The fractional and integer parts of $x$ in a two-item tuple. Both parts have the same sign as $x$ . The integer part is returned as a float.
pow(x, y)	The value of x**y.
round(x [,n])	x rounded to n digits from the decimal point. Python rounds away from zero as a tie-breaker: round(0.5) is 1.0 and round(-0.5) is -1.0.
sqrt(x)	The square root of x for $x > 0$ .
1 0+ 1.0 100 th oh of the office of the detail	00 6:50:050 :5 40:0:1

Let us learn about these functions in detail.

## Number abs() Method

### Description

zero. The **abs()** method returns the absolute value of x i.e. the positive distance between x and

#### Syntax

Following is the syntax for abs() method-

```
abs(
```

#### **Parameters**

x - This is a numeric expression.

## **Return Value**

This method returns the absolute value of x.

#### Example

The following example shows the usage of the abs() method.

```
print ("abs(100.12) :
                       print ("abs(-45) : ",
                                                #!/usr/bin/python3
", abs(100.12))
                        abs(-45))
```

When we run the above program, it produces the following result-

```
abs(100.12) :
            45
100.12
```

## Number ceil() Method

### **Description**

The **ceil()** method returns the ceiling value of x i.e. the smallest integer not less than x.

#### **Syntax**

Following is the syntax for the ceil() method-

```
math.ceil(x)
                  import math
```

**Note:** This function is not accessible directly, so we need to import math module and then we need to call this function using the math static object.

### **Parameters**

x - This is a numeric expression.

## **Return Value**

This method returns the smallest integer not less than x.

#### Example

The following example shows the usage of the ceil() method.

```
print ("math.ceil(math.pi) :
                                     print ("math.ceil(100.72) : ", math.ceil(100.72))
                                                                              print ("math.ceil(100.12) :
                                                                                                                   print ("math.ceil(-45.17) :
                                                                                                                                                         import math
                                                                                                                                                                                                #!/usr/bin/python3
                                                                                                                                                         # This will import math module
                                                                              ", math.ceil(100.12))
                                                                                                                   ", math.ceil(-45.17))
", math.ceil(math.pi))
```

When we run the above program, it produces the following result-

```
math.ceil(math.pi) :
                  math.ceil(100.72) :
                                    math.ceil(100.12) :
                                                       math.ceil(-45.17) :
                   101
                                      101
                                                        -45
4
```

## Number exp() Method

### **Description**

The **exp()** method returns exponential of  $x: e^x$ .

#### Syntax

Following is the syntax for the exp() method-

```
math.exp(x)
                   import math
```

module and then we need to call this function using the math static object. Note: This function is not accessible directly. Therefore, we need to import the math

### **Parameters**

X - This is a numeric expression.

## **Return Value**

This method returns exponential of x: ex.

#### Example

The following example shows the usage of exp() method

```
print
      print
                                print
                                                                                    print ("math.exp(-45.17) :
                                                                                                                import math
                                                                                                                                             #!/usr/bin/python3
  ("math.exp(math.pi) :
                             ("math.exp(100.72) : ", math.exp(100.72))
                                                        ("math.exp(100.12) : ", math.exp(100.12))
                                                                                                                 # This will import math module
                                                                                    ", math.exp(-45.17))
ς=
    math.exp(math.pi))
```

When we run the above program, it produces the following result-

```
math.exp(math.pi)
                        math.exp(100.72)
                                                  math.exp(100.12)
                                                                               math.exp(-45.17)
                          ••

## Number fabs() Method

### Description

there are differences between the two functions. They are-The fabs() method returns the absolute value of x. Although similar to the abs() function,

- abs() is a built in function whereas fabs() is defined in math module
- fabs() function works only on float and integer whereas abs() works with complex number also.

#### Syntax

Following is the syntax for the fabs() method-

```
math.fabs(x)
                     import math
```

**Note:** This function is not accessible directly, so we need to import the math module and then we need to call this function using the math static object.

### **Parameters**

x - This is a numeric value.

## **Return Value**

This method returns the absolute value of x.

#### Example

The following example shows the usage of the fabs() method.

```
print
                                                 print
 print
                                                                         print ("math.fabs(-45.17)
                                                                                                                           #!/usr/bin/python3
                                                                                                    import math
                       ("math.fabs(100.72)
                                                 ("math.fabs(100.12)
("math.fabs(math.pi) :
                                                                                                    # This will
                                                                                                   import math module
                                                                         ", math.fabs(-45.17))
                       math.fabs(100.72))
                                                 math.fabs(100.12))
math.fabs(math.pi))
```

When we run the above program, it produces following result-

```
math.fabs(math.pi) :
                                          math.fabs(100) :
                       math.fabs(100.72) :
                                                                  math.fabs(-45.17)
                                             100.0
                                                                   45.17
                         100.72
   3.141592653589793
```

## Number floor() Method

### Description

The **floor()** method returns the floor of  $\mathbf{x}$  i.e. the largest integer not greater than  $\mathbf{x}$ .

#### Syntax

Following is the syntax for the floor() method-

```
math.floor( x
                    import math
```

then we need to call this function using the math static object. Note: This function is not accessible directly, so we need to import the math module and

#### **Parameters**

x - This is a numeric expression.

## **Return Value**

This method returns the largest integer not greater than x.

#### Example

The following example shows the usage of the floor() method.

```
print
print ("math.floor(math.pi) : ", math.floor(math.pi))
                                                                              print ("math.floor(100.12) :
                                                                                                                                                           import math
                                                                                                                                                                                             #!/usr/bin/python3
                                                                                                                 ("math.floor(-45.17) : ", math.floor(-45.17))
                                       ("math.floor(100.72) :
                                                                                                                                                         # This will import math module
                                      ", math.floor(100.72))
                                                                               math.floor(100.12))
```

When we run the above program, it produces the following result-

```
math.floor(math.pi) :
                   math.floor(100.72) :
                                        math.floor(100.12)
                                                          math.floor(-45.17)
                    100
                                         100
                                                           -46
 ω
```

## Number log() Method

### Description

The log() method returns the natural logarithm of x, for x > 0.

#### **Syntax**

Following is the syntax for the log() method-

```
math.log( x
                    import math
```

**Note:** This function is not accessible directly, so we need to import the math module and then we need to call this function using the math static object.

#### **Parameters**

x - This is a numeric expression.

## **Return Value**

This method returns natural logarithm of x, for x > 0.

#### Example

The following example shows the usage of the log() method.

```
print ("math.log(100.72) : ", math.log(100.72))
                                                                                        print ("math.log(100.12) : ", math.log(100.12))
print ("math.log(math.pi) : ", math.log(math.pi))
                                                                                                                                           import math
                                                                                                                                                                                         #!/usr/bin/python3
                                                                                                                                           # This will import math module
```

When we run the above program, it produces the following result-

```
math.log(math.pi) : 1.1447298858494002
                               math.log(100.72) :
                                                                  math.log(100.12) :
                                    4.612344389736092
                                                                      4.6063694665635735
```

## Number log10() Method

### Description

The log10() method returns base-10 logarithm of x for x > 0

#### Syntax

Following is the syntax for log10() method-

```
math.log10( \times
                      import math
```

then we need to call this function using the math static object Note: This function is not accessible directly, so we need to import the math module and

### **Parameters**

x - This is a numeric expression.

## **Return Value**

This method returns the base-10 logarithm of x for x > 0.

#### Example

The following example shows the usage of the log10() method.

```
print
                                                                           print
   print
                                                                                                              print ("math.log10(100.12) : ", math.log10(100.12))
                                                                                                                                                                                           #!/usr/bin/python3
                                                                                                                                                       import math
                                    ("math.log10(119) : ", math.log10(119))
                                                                        ("math.log10(100.72) : ", math.log10(100.72))
("math.log10(math.pi) : ", math.log10(math.pi))
                                                                                                                                                    # This will import math module
```

When we run the above program, it produces the following result-

```
math.log10(math.pi) : 0.49714987269413385
                                   math.log10(119) : 2.0755469613925306
                                                                          math.log10(100.72) :
                                                                                                               math.log10(100.12) :
                                                                            2.003115717099806
                                                                                                                  2.0005208409361854
```

## Number max() Method

### **Description**

infinity. The max() method returns the largest of its arguments i.e. the value closest to positive

#### Syntax

Following is the syntax for max() method-

```
max( x, y, z, .... )
```

#### **Parameters**

- x This is a numeric expression.
- y This is also a numeric expression.
- **z** This is also a numeric expression.

## **Return Value**

This method returns the largest of its arguments.

#### Example

The following example shows the usage of the max() method.

```
print ("max(-20, 100, 400) : ", max(-20, 100, 400))
                                                                                                    print ("max(80, 100, 1000) : ", max(80, 100, 1000))
                                                                                                                                         #!/usr/bin/python3
                                  ("max(-80, -20, -10) : ",
("max(0, 100, -400) :
 max(0,
                                  max(-80, -20, -10))
    100, -400))
```

When we run the above program, it produces the following result-

```
max(80, 100, 1000) :
 max(-80,
               max(-20, 100, 400) :
-20, -10)
                 400
                                  1000
 -10
```

```
max(0, 100,
-400) :
 100
```

## Number min() Method

### **Description**

infinity. The method **min()** returns the smallest of its arguments i.e. the value closest to negative

#### Syntax

Following is the syntax for the min() method-

```
min( x,
ζ
ζ,
: . .
```

### **Parameters**

- x This is a numeric expression.
- y This is also a numeric expression.
- **z** This is also a numeric expression.

## **Return Value**

This method returns the smallest of its arguments.

#### Example

The following example shows the usage of the **min()** method.

```
print
 print
                                        print ("min(-20, 100,
                                                             print ("min(80, 100, 1000) : ", min(80, 100, 1000))
                                                                                  #!/usr/bin/python3
                     ("min(-80, -20, -10) : ", min(-80, -20, -10))
("min(0, 100, -400) :
                                            400) :
                                  . =
min(0, 100, -400))
                                         min(-20,
                                        100,
                                           400))
```

When we run the above program, it produces the following result-

```
min(-80, -20, -10) :
                            min(-20, 100,
min(0, 100,
                                          min(80, 100, 1000) :
-400) :
                            400)
 -400
               -80
                             -20
                                            80
```

## Number modf() Method

### Description

parts have the same sign as x. The integer part is returned as a float. The modf() method returns the fractional and integer parts of x in a two-item tuple. Both

#### Syntax

Following is the syntax for the modf() method-

```
math.modf(x)
                   import math
```

**Note:** This function is not accessible directly, so we need to import the math module and then we need to call this function using the math static object.

### **Parameters**

x - This is a numeric expression.

## **Return Value**

parts have the same sign as x. The integer part is returned as a float. This method returns the fractional and integer parts of x in a two-item tuple. Both the

#### Example

The following example shows the usage of the **modf()** method

```
print
                                             print ("math.modf(119) : ", math.modf(119))
                                                                                        print ("math.modf(100.72) : ", math.modf(100.72))
                                                                                                                                                                                 import math
                                                                                                                                                                                                                        #!/usr/bin/python3
("math.modf(math.pi) : ", math.modf(math.pi))
                                                                                                                                 ("math.modf(100.12) : ", math.modf(100.12))
                                                                                                                                                                               # This will import math module
```

When we run the above program, it produces the following result-

```
math.modf(math.pi) :
                            math.modf(119)
                                                      math.modf(100.72)
                                                                              math.modf(100.12) :
                            ••
                            (0.0, 119.0)
                                                    (0.719999999999989, 100.0)
                                                                              (0.120000000000000455, 100.0)
  (0.14159265358979312,

```

## Number pow() Method

## **Return Value**

This method returns the value of xy.

#### Example

The following example shows the usage of the **pow()** method.

```
print
                                                                 print
                       print
                                                                                          import math
                                                                                                                #!/usr/bin/python3
                    ("math.pow(2, 4) : ", math.pow(2,
                                            ("math.pow(100,
                                                                    ("math.pow(100,
("math.pow(3, 0) : ", math.pow(3, 0))
                                                                                          # This
                                                                                        will import math module
                                            -2) :
                                                                 2) : ", math.pow(100, 2))
                                            ", math.pow(100,
                       4))
```

When we run the above program, it produces the following result-

```
math.pow(3, 0):
              math.pow(2,
                            math.pow(100,
                                         math.pow(100,
              4
                                           2) :
                            -2) : 0.0001

## Number round() Method

### **Description**

point. round() is a built-in function in Python. It returns x rounded to n digits from the decimal

#### Syntax

Following is the syntax for the round() method-

```
round( x
凸
```

### **Parameters**

- x This is a numeric expression.
- $\boldsymbol{n}$  Represents number of digits from decimal point up to which  $\boldsymbol{x}$  is to be rounded. Default is 0.

## **Return Value**

This method returns x rounded to n digits from the decimal point.

#### Example

The following example shows the usage of **round()** method.

```
print
   print
                                                                                      print
                              print
                                                                                                                print ("round(70.23456) :
                                                                                                                                           #!/usr/bin/python3
                            ("round(100.000056, 3): ", round(100.000056, 3))
                                                       ("round(80.264, 2) : ", round(80.264, 2))
                                                                                   ("round(56.659,1) : ",
 ("round(-100.000056,
                                                                                                               ", round(70.23456))
3) : ", round(-100.000056, 3))
                                                                                      round(56.659,1))
```

When we run the above program, it produces the following result-

```
round(-100.000056, 3):
                  round(100.000056,
                                       round(80.264, 2):
                                                           round(56.659,1) :
                                                                              round(70.23456)
                  3) : 100.0
                                                            56.7
                                                                                70
                                        80.26
  -100.0
```

## Number sqrt() Method

#### Description

The **sqrt()** method returns the square root of x for x > 0.

#### Syntax

Following is the syntax for sqrt() method-

```
math.sqrt( x )
                       import math
```

then we need to call this function using the math static object. Note: This function is not accessible directly, so we need to import the math module and

### **Parameters**

x - This is a numeric expression.

## Return Value

This method returns square root of x for x > 0.

#### Example

The following example shows the usage of sqrt() method.

```
print ("math.sqrt(math.pi) : ", math.sqrt(math.pi))
                                           print ("math.sqrt(7) : ", math.sqrt(7))
                                                                                      print ("math.sqrt(100) : ", math.sqrt(100))
                                                                                                                                                                                #!/usr/bin/python3
                                                                                                                                        import math
                                                                                                                                     # This will import math module
```

When we run the above program, it produces the following result-

```
math.sqrt(math.pi) : 1.7724538509055159
                           math.sqrt(7) :
                                                       math.sqrt(100)
                             2.6457513110645907
                                                        10.0
```

## **Random Number Functions**

Random numbers are used for games, simulations, testing, security, a applications. Python includes the following functions that are commonly used. security, and privacy

Function	Description
choice(seq)	A random item from a list, tuple, or string.
randrange ([start,] stop [,step])	A randomly selected element from range(start, stop, step).
random()	A random float r, such that 0 is less than or equal to r and r is less than 1.
seed([x])	Sets the integer starting value used in generating random numbers. Call this function before calling any other random module function. Returns None.
shuffle(Ist)	Randomizes the items of a list in place. Returns None.
uniform(x, y)	A random float r, such that x is less than or equal to r and r is less than y.

## Number choice() Method

### Description

The **choice()** method returns a random item from a list, tuple, or string.

#### Syntax

Following is the syntax for choice() method-

```
choice( seq )
```

and then we need to call this function using the random static object. Note: This function is not accessible directly, so we need to import the random module

### **Parameters**

seq - This could be a list, tuple, or string...

## **Return Value**

This method returns a random item

#### Example

The following example shows the usage of the choice() method.

```
print
                                                  2, 3,
                                                                   print ("returns random element from list [1, 2, 3, 5, 9]) : ", random.choice([1,
                                                                                                                                             #!/usr/bin/python3
random.choice('Hello World'))
                                                                                                                        import random
                                                                                            ("returns a
                                                                                           random number from range(100) :
                           from
                         string
                                                                                           ",random.choice(range(100)))
                           'Hello
                           World'
```

When we run the above program, it produces ۵ result similar to the following-

```
returns
                    returns
random character from string 'Hello World' :
                    random
                                    a random number from range(100) :
                  element from list [1,
                  2,
                  ω
                  5, 9])
                   ..
                    9
  7
```

## Number randrange() Method

### Description

The randrange() method returns a randomly selected element from range(start, stop,

#### Syntax

Following is the syntax for the randrange() method-

```
randrange
 ([start,] stop [,step])
```

and then we need to call this function using the random static object. Note: This function is not accessible directly, so we need to import the random module

#### **Parameters**

- start Start point of the range. This would be included in the range. Default is 0.
- **stop** Stop point of the range. This would be excluded from the range.
- ${f step}$  Value with which number is incremented. Default is 1.

## **Return Value**

This method returns a random item from the given range.

#### Example

The following example shows the usage of the randrange() method

```
print ("randrange(100) : ", random.randrange(100))
                                                                            print ("randrange(1,100, 2) : ", random.randrange(1,
                                                                                                                        # randomly select an odd number between 1-100
                                                                                                                                                                import random
                                                                                                                                                                                                   #!/usr/bin/python3
                                          randomly select
                                          a number between 0-99
                                                                             100,
                                                                                2))
```

When we run the above program, it produces the following result-

```
randrange(100)
            randrange(1,100,
 ..
            2)
  93
              83
```

## Number random() Method

### Description

The random() method returns a random floating point number in the range [0.0, 1.0].

#### Syntax

Following is the syntax for the random() method-

```
random ( )
```

and then we need to call this function using the random static object. Note: This function is not accessible directly, so we need to import the random module

### **Parameters**

Z

## **Return Value**

This method returns a random float r, such that 0.0 <= 7 ٨ 1.0

#### Example

The following example shows the usage of the random() method

```
print ("random() : ", random.random())
                                                                              print ("random() : ", random.random())
                                                                                                                      # First random number
                                          # Second random number
                                                                                                                                                               import random
                                                                                                                                                                                                   #!/usr/bin/python3
```

When we run the above program, it produces the following result-

```
random() :
                    random()
  0.309090465205
                    0.281954791393
```

## Number seed() Method

### **Description**

before calling any other random module function. The seed() method initializes the basic random number generator. Call this function

#### Syntax

Following is the syntax for the seed() method-

```
([×]
[2]
```

Note: This function initializes the basic random number generator.

### **Parameters**

- ${\bf x}$  This is the seed for the next random number. If omitted, then it takes system time to generate the next random number. If  ${\bf x}$  is an int, it is used directly.
- converted in int. Version 1 used hash() of x. str, byte or byte array object gets

## **Return Value**

This method does not return any value.

#### Example

The following example shows the usage of the seed() method.

```
print
print ("random number with string seed", random.random())
                                                                                                                                                         print ("random number with default seed", random.random())
                                                                                                                                                                                                                                                                            #!/usr/bin/python3
                                      random.seed("hello",2)
                                                                                                                       random.seed(10)
                                                                                                                                                                                                  random.seed()
                                                                                                                                                                                                                                         import random
                                                                            ("random number with int seed",
                                                                               random.random())
```

When we run above program, it produces following result-

```
random number with string seed 0.3537754404730722
                                                                     random number with int seed 0.5714025946899135
                                                                                                                                                      random number with default seed 0.2524977842762465
```

## Number shuffle() Method

### Description

The **shuffle()** method randomizes the items of a list in place.

#### **Syntax**

Following is the syntax for the shuffle() method-

```
shuffle
(lst,[random])
```

Note: This function is not accessible directly, so we need to import the shuffle module and then we need to call this function using the random static object.

#### Parameters

- Ist This could be a list or tuple.
- random This is an optional 0 argument function returning float between 0.0 1.0. Default is None

## **Return Value**

This method returns reshuffled list.

#### Example

The following example shows the usage of the shuffle() method.

```
print ("Reshuffled list
print ("Reshuffled list
                    random.shuffle(list)
                                                         random.shuffle(list)
                                                                            list =
                                                                                             import random
                                                                                                              #!/usr/bin/python3
                                                                          [20, 16, 10, 5];
                                      ••
  ..
                                  _=
ζ=
   list)
                                      list)
```

When we run the above program, it produces the following result-

```
reshuffled list :
          Reshuffled
          list
[20,
        [16,
        5,
2
10,
         10,
16]
        20]
```

## Number uniform() Method

### Description

The  $\mathbf{uniform()}$  method returns a random float  $\mathbf{r}$ , such that  $\mathbf{x}$  is less than or equal to  $\mathbf{r}$  and  $\mathbf{r}$  is less than  $\mathbf{y}$ .

#### Syntax

Following is the syntax for the uniform() method-

```
uniform(x,
5
```

and then we need to call this function using the random static object. **Note:** This function is not accessible directly, so we need to import the uniform module

### **Parameters**

- x Sets the lower limit of the random float.
- y Sets the upper limit of the random float.

## **Return Value**

This method returns a floating point number r such that x <= r < y.

#### Example

The following example shows the usage of the uniform() method

```
#!/usr/bin/python3
import random
```

```
print
print ("Random Float uniform(7,
                   ("Random Float uniform(5,
 14) : ",
                    10)
                  _=
random.uniform(7, 14))
                   random.uniform(5,
                   10))
```

Let us run the above program. This will produce the following result-

```
Random Float uniform(7, 14) :
                       Random Float uniform(5,
                          10) :
12.5326369199
                          5.52615217015
```

## **Trigonometric Functions**

Python includes the following functions that perform trigonometric calculations.

Function	Description
acos(x)	Return the arc cosine of $x$ , in radians.
asin(x)	Return the arc sine of $x$ , in radians.
atan(x)	Return the arc tangent of $x$ , in radians.
atan2(y, x)	Return atan(y $/ x$ ), in radians.
(x)soo	Return the cosine of $x$ radians.
hypot(x, y)	Return the Euclidean norm, $sqrt(x*x + y*y)$ .
sin(x)	Return the sine of $x$ radians.
tan(x)	Return the tangent of $\boldsymbol{x}$ radians.
degrees(x)	Converts angle x from radians to degrees.
radians(x)	Converts angle x from degrees to radians.

## Number acos() Method

### **Description**

The acos() method returns the arc cosine of x in radians.

#### **Syntax**

Following is the syntax for acos() method-

```
acos(x)
```

then we need to call this function using the math static object. Note: This function is not accessible directly, so we need to import the math module and

### **Parameters**

generate 'math domain error'. **x** - This must be a numeric value in the range -1 to <u>:-</u> If x is greater than 1 then it will

## **Return Value**

This method returns arc cosine of x, in radians.

#### Example

The following example shows the usage of the acos() method.

```
print
                                                               print
print ("acos(1) : ",
                                         print ("acos(0) : ",
                                                                                                       #!/usr/bin/python3
                                                                                    import math
                     ("acos(-1) : ",
                                                                ("acos(0.64) :
math.acos(1))
                                          math.acos(0))
                    math.acos(-1))
                                                                math.acos(0.64))
```

When we run the above program, it produces the following result-

```
acos(-1) :
                                   acos(0) :
                                                 acos(0.64) :
acos(1) :
 0.0
                                   1.57079632679
                  3.14159265359
                                                     0.876298061168
```

## Number asin() Method

### Description

The asin() method returns the arc sine of x (in radians).

#### **Syntax**

Following is the syntax for the asin() method-

```
asin(x)
```

**Note:** This function is not accessible directly, so we need to import the math module then we need to call this function using the math static object. and

### **Parameters**

 ${f x}$  - This must be a numeric value in the range -1 to 1. generate 'math domain error'. If x is greater than 1 then it will

## **Return Value**

This method returns arc sine of x, in radians.

#### Example

The following example shows the usage of the asin() method.

```
print
                                                            print
                                      print ("asin(0) : ",
                                                                                                 #!/usr/bin/python3
                                                                                import math
("asin(1) : ",
                                                           ("asin(0.64) :
                   ("asin(-1) : ",
math.asin(1))
                                        math.asin(0))
                   math.asin(-1))
                                                            math.asin(0.64))
```

When we run the above program, it produces the following result-

```
asin(0)
asin(1) :
                   asin(-1):
                                                     asin(0.64) :
1.5707963267
                   -1.57079632679
                                                       0.694498265627
```

## Number atan() Method

### **Description**

The atan() method returns the arc tangent of x, in radians.

#### Syntax

Following is the syntax for atan() method-

```
atan(x)
```

**Note:** This function is not accessible directly, so we need to import the math module and then we need to call this function using the math static object.

### **Parameters**

x - This must be a numeric value

## **Return Value**

This method returns arc tangent of x, in radians

#### Example

The following example shows the usage of the atan() method.

```
print
                                    print
                                                      print
                                                                        print
                                                                                                           #!/usr/bin/python3
                                                                                         import math
("atan(1) : ",
                                   ("atan(10) : ",
                                                     ("atan(0) : ",
                                                                         ("atan(0.64) :
                  ("atan(-1) : ",
math.atan(1))
                                                       math.atan(0))
                                    math.atan(10))
                 math.atan(-1))
                                                                       math.atan(0.64))
```

When we run the above program, it produces the following result-

```
atan(0)
                                                                     atan(0.64) :
atan(1):
                 atan(-1) :
                                   atan(10)
                                                       0.0
0.785398163397
                 -0.785398163397
                                   1.4711276743
                                                                       0.569313191101
```

## Number atan2() Method

### **Description**

The **atan2()** method returns atan(y / x), in radians.

#### Syntax

Following is the syntax for atan2() method-

```
atan2(y,
Š
```

then we need to call this function using the math static object. Note: This function is not accessible directly, so we need to import the math module and

### **Parameters**

- y This must be a numeric value.
- x This must be a numeric value.

## **Return Value**

This method returns atan(y / x), in radians.

#### Example

The following example shows the usage of atan2() method.

```
print
                                                    print
                                                                              print
                                                                                                      print
                                                                                                                                                      #!/usr/bin/python3
                                                                                                                                import math
("atan2(10,20) : ",
                                                 ("atan2(5,5) : ",
                                                                          ("atan2(0.50,0.50) : ", math.atan2(0.50,0.50))
                                                                                                       ("atan2(-0.50,-0.50) : ",
                         ("atan2(-10,10) : ",
                                                    math.atan2(5,5))
  math.atan2(10,20))
                          math.atan2(-10,10))
                                                                                                       math.atan2(-0.50,-0.50))
```

When we run the above program, it produces the following result-

```
atan2(-10,10) : -0.785398163397
                                                                                        atan2(0.50,0.50) :
                                                            atan2(5,5): 0.785398163397
                                                                                                                     atan2(-0.50,-0.50) :
atan2(10,20) :
  0.463647609001
                                                                                           0.785398163397
                                                                                                                         -2.35619449019
```

## Number cos() Method

### Description

The cos() method returns the cosine of x radians.

#### Syntax

Following is the syntax for cos() method-

```
cos(x)
```

**Note:** This function is not accessible directly, so we need to import the math module and then we need to call this function using the math static object.

#### **Parameters**

x - This must be a numeric value

## **Return Value**

the angle. This method returns a numeric value between -1 and 1, which represents the cosine of

#### Example

The following example shows the usage of cos() method.

```
print
  print
                                         print
                                                                                  print
                                                           print ("cos(-3) : ",
                                                                                                                         #!/usr/bin/python3
                                                                                                     import math
                                                                                ("cos(3) : ",
                   ("cos(math.pi) : ", math.cos(math.pi))
                                        ("cos(0): ",
("cos(2*math.pi) : ",
                                                                               math.cos(3))
                                         math.cos(0))
                                                            math.cos(-3))
math.cos(2*math.pi))
```

When we run the above program, it produces the following result-

```
cos(3)
                 cos(math.pi) :
                                     cos(0) :
                                                         cos(-3):
cos(2*math.pi) : 1.0
                                                                              -0.9899924966
                                                          -0.9899924966
```

## Number hypot() Method

### Description

The method hypot() return the Euclidean norm, sqrt(x\*x + y\*y). This is length of vector from origin to point (x,y)

#### Syntax

Following is the syntax for hypot() method-

```
hypot(x, y)
```

**Note:** This function is not accessible directly, so we need to import math module and then we need to call this function using math static object.

### **Parameters**

- x This must be a numeric value
- y This must be a numeric value.

## **Return Value**

This method returns Euclidean norm, sqrt(x\*x + y\*y).

#### Example

The following example shows the usage of hypot() method.

```
print
                       print ("hypot(-3, 3) : ",
                                                             import math
                                                                              #!/usr/bin/python3
                                        ("hypot(3, 2) : ",
     ("hypot(0,
      2) :
. . =
                                          math.hypot(3, 2))
      math.hypot(0,
                       math.hypot(-3, 3))
```

When we run the above program, it produces the following result-

```
hypot(0,
             hypot(-3, 3):
                            hypot(3,
                            2) :
2)
 2.0
                             3.60555127546
              4.24264068712
```

## Number sin() Method

### Description

The sin() method returns the sine of x, in radians.

#### Syntax

Following is the syntax for sin() method-

```
sin(x)
```

**Note**: This function is not accessible directly, so we need to import the math module and then we need to call this function using the math static object.

### **Parameters**

x - This must be a numeric value

## **Return Value**

parameter x. This method returns a numeric value between -1 and 1, which represents the sine of the

#### Example

The following example shows the usage of sin() method.

```
print ("sin(0) : ",
                                            print ("sin(3) : "
                     print ("sin(-3) : ",
                                                                      import math
                                                                                              #!/usr/bin/python3
math.sin(0))
                                              math.sin(3))
                     math.sin(-3))
```

```
print ("sin(math.pi/2) : ",
                    print
                    ("sin(math.pi) :
                _=
                     math.sin(math.pi))
math.sin(math.pi/2))
```

When we run the above program, it produces the following result-

```
sin(-3)
sin(math.pi/2)
                                   sin(0):
                 sin(math.pi) :
                                                                     sin(3):
                                    0.0
                                                                      0.14112000806
                                                     -0.14112000806
  ..
                   1.22460635382e-16
```

## Number tan() Method

### **Description**

The tan() method returns the tangent of x radians.

#### **Syntax**

Following is the syntax for tan() method

```
tan(x)
```

**Note:** This function is not accessible directly, so we need to import math module and then we need to call this function using math static object.

### **Parameters**

x - This must be a numeric value

## **Return Value**

the parameter x. This method returns a numeric value between -1 and 1, which represents the tangent of

#### Example

The following example shows the usage of tan() method.

```
print
                                    print
                                                                           print
print
                   print
                                                                                                              #!/usr/bin/python3
                                                                                               import math
                                                       ("tan(-3) : ",
                                                                         ("(tan(3) : ",
("tan(math.pi/2) :
                  ("tan(math.pi) : ",
                                    ("tan(0) : ",
                                     math.tan(0))
                                                        math.tan(-3))
                                                                            math.tan(3))
", math.tan(math.pi/2))
                   math.tan(math.pi))
```

```
print ("tan(math.pi/4) : ",
 math.tan(math.pi/4))
```

When we run the above program, it produces the following result-

```
print
                                                                                    print
                     print
                                          print
                                                               print
                                                                                                         print
("tan(math.pi/4) : ", math.tan(math.pi/4))
                    ("tan(math.pi/2) : ",
                                         ("tan(math.pi) : ", math.tan(math.pi))
                                                              ("tan(0) : ",
                                                                                  ("tan(-3) : ",
                                                                                                        ("(tan(3) : ",
                                                               math.tan(0))
                                                                                  math.tan(-3))
                                                                                                       math.tan(3))
                     math.tan(math.pi/2))
```

# Number degrees() Method

## **Description**

The **degrees()** method converts angle x from radians to degrees..

#### Syntax

Following is the syntax for degrees() method-

```
degrees(x)
```

then we need to call this function using the math static object. Note: This function is not accessible directly, so we need to import the math module and

## **Parameters**

x - This must be a numeric value

## **Return Value**

This method returns the degree value of an angle.

#### Example

The following example shows the usage of degrees() method

```
print ("degrees(math.pi/2) : ",
                           print
                                                       print
                                                                                                             print ("degrees(3) : ",
                                                                                                                                                                    #!/usr/bin/python3
                                                                                 print ("degrees(-3) : ",
                                                                                                                                             import math
                           ("degrees(math.pi) : ", math.degrees(math.pi))
                                                       ("degrees(0) :
                                                                                                             math.degrees(3))
                                                      math.degrees(0))
                                                                                 math.degrees(-3))
 math.degrees(math.pi/2))
```

```
print ("degrees(math.pi/4) : ",
 math.degrees(math.pi/4))
```

When we run the above program, it produces the following result-

```
degrees(math.pi/4) : 45.0
                                        degrees(math.pi) :
                                                            degrees(0)
                                                                               degrees(-3)
                                                                                                  degrees(3) :
                    degrees(math.pi/2) :
                                                            ••
                                                                                 ••
                                                              0.0
                                                                                                     171.88733853924697
                                                                                -171.88733853924697
                                          180.0
                     90.0
```

# Number radians() Method

## Description

The **radians()** method converts angle x from degrees to radians.

#### Syntax

Following is the syntax for radians() method-

```
radians(x)
```

then we need to call this function using the math static object. Note: This function is not accessible directly, so we need to import the math module and

## **Parameters**

x - This must be a numeric value

## **Return Value**

This method returns radian value of an angle.

#### Example

The following example shows the usage of radians() method.

```
print
print ("radians(math.pi/2) : ",
                         print
                                                                                                   print ("radians(3) : ",
                                                                                                                                                      #!/usr/bin/python3
                                                                          print ("radians(-3) : ",
                                                                                                                                 import math
                        ("radians(math.pi) :
                                                  ("radians(0) :
                                                                                                    math.radians(3))
                                                     math.radians(0))
                                                                          math.radians(-3))
                       ", math.radians(math.pi))
 math.radians(math.pi/2))
```

```
print ("radians(math.pi/4) : ",
 math.radians(math.pi/4))
```

When we run the above program, it produces the following result-

```
radians(math.pi/4) :
                                       radians(math.pi) :
                                                           radians(0)
                                                                             radians(-3)
                    radians(math.pi/2) :
                                                                                                  radians(3) :

# **Mathematical Constants**

The module also defines two mathematical constants-

Constants	Description
pi	The mathematical constant pi.
Ф	The mathematical constant e.

# 10. Python 3 — Strings

Creating strings is as simple as assigning a value to a variable. For example-Strings are amongst the most popular types in Python. We can create them simply by enclosing characters in quotes. Python treats single quotes the same as double quotes.

```
var2
  П
 "Python
              'Hello World!'
Programming"
```

# **Accessing Values in Strings**

Python does not support a character type; these are treated as strings of length one, thus also considered a substring.

obtain your substring. For example-To access substrings, use the square brackets for slicing along with the index or indices to

```
print ("var2[1:5]: ", var2[1:5])
                                                                                                           #!/usr/bin/python3
                          ("var1[0]: ",
                                                      "Python Programming"
                                                                                   'Hello World!'
                           var1[0])
```

When the above code is executed, it produces the following result-

```
var2[1:5]:
             var1[0]:
ytho
```

## **Updating Strings**

value can be related to its previous value or to a completely different string altogether. You can "update" an existing string by (re)assigning a variable to another string. The new For example-

```
print ("Updated String :- ", var1[:6] + 'Python')
                                                                                       #!/usr/bin/python3
                                              'Hello World!'
```

When the above code is executed, it produces the following result-

```
Updated String
Hello Pythor
```

## **Escape Characters**

Following table is a list of escape or non-printable characters that can be represented with backslash notation.

An escape character gets interpreted; in a single quoted as well as double quoted strings.

notation o	Ь	\cx	\C-x	\e	\f	\M-\C-x	'n	\nnn	\r .	\s	
character 0x07 0x08	0x08			0x1b	0x0c		0x0a		0x0d	0x20	0×09
Bell or alert Backspace	Backspace	Control-x	Control-x	Escape	Formfeed	Meta-Control-x	Newline	Octal notation, where n is in the range 0.7	Carriage return	Space	Tab

\xnn	×	\\
		0×0b
Hexadecimal notation, where n is in the range 0.9, a.f, or A.F	Character x	Vertical tab

# String Special Operators

Assume string variable  ${\bf a}$  holds 'Hello' and variable  ${\bf b}$  holds 'Python', then-

r/R Raw String characters. same as for raw string	not in Memb	in Memb	[ : ] Range range	[] Slice ·	* Repetition multiple co	+ Concater operator	Operator
Raw String - Suppresses actual meaning of Escape characters. The syntax for raw strings is exactly the same as for normal strings with the exception of the raw string operator, the letter "r," which precedes the quotation marks. The "r" can be lowercase (r) or uppercase (R) and must be placed immediately proceding the first quota mark.	Membership - Returns true if a character does not exist in the given string	Membership - Returns true if a character exists in the given string	Slice - Gives the characters from the given	Slice - Gives the character from the given index	Repetition - Creates new strings, concatenating multiple copies of the same string	Concatenation - Adds values on either side of the operator	Description
print r'\n' prints \n and R'\n'prints \n	M not in a will give 1	H in a will give 1	a[1:4] will give ell	a[1] will give e	a*2 will give - HelloHello	a + b will give HelloPython	Example

%	
Format - Performs String formatting	
See next section	

# String Formatting Operator

One of Python's coolest features is the string format operator %. This operator is unique to strings and makes up for the pack of having functions from C's printf() family. Following is a simple example -

```
print ("My name is
               #!/usr/bin/python3
 %
and weight is %d kg!"
 %
('Zara',
 21))
```

When the above code is executed, it produces the following result

```
My name is Zara and weight is 21 kg!
```

Here is the list of complete set of symbols which can be used along with %-

%e e>	%X he	%x he	%o	%u ur	%d si	%i si	%s st	%c ch	Format Symbol
exponential notation (with lowercase 'e')	hexadecimal integer (UPPERcase letters)	hexadecimal integer (lowercase letters)	octal integer	unsigned decimal integer	signed decimal integer	signed decimal integer	string conversion via str() prior to formatting	character	Conversion

%G	%g	%f	%E
the shorter of %f and %E	the shorter of %f and %e	floating point real number	exponential notation (with UPPERcase 'E')

Other supported symbols and functionality are listed in the following table-

Symbol	Functionality
*	argument specifies width or precision
•	left justification
+	display the sign
<sp></sp>	leave a blank space before a positive number
#	add the octal leading zero ( '0' ) or hexadecimal leading '0x' or '0X', depending on whether 'x' or 'X' were used.
0	pad from left with zeros (instead of spaces)
%	'%%' leaves you with a single literal '%'
(var)	mapping variable (dictionary arguments)
m.n.	m is the minimum total width and n is the number of digits to display after the decimal point (if appl.)

## Triple Quotes

Python's triple quotes comes to the rescue by allowing strings to span multiple including verbatim NEWLINEs, TABs, and any other special characters. lines,

The syntax for triple quotes consists of three consecutive single or double quotes.

```
print (para_str)
                                                                                                                                                        this within the brackets [\ \ \ ], or just a NEWLINE within
                                                                                                                                                                                                            NEWLINEs within the string, whether explicitly given like
                                                                                                                                                                                                                                                                                                                                                                      para_str =
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                 #!/usr/bin/python3
                                                                                                        the variable assignment will also show up.
                                                                                                                                                                                                                                                                  TAB ( \t ) and they will show up that way when displayed.
                                                                                                                                                                                                                                                                                                                      several lines and non-printable characters such as
                                                                                                                                                                                                                                                                                                                                                                           """this is
                                                                                                                                                                                                                                                                                                                                                                           a long string that is made up
                                                                                                                                                                                                                                                                                                                                                                           ٩f
```

at the end of the string between the "up." and closing triple quotes. Also note that When the above code is executed, it produces the following result. Note how every single special character has been converted to its printed form, right down to the last NEWLINE code (\n) -NEWLINEs occur either with an explicit carriage return at the end of a line or its escape

```
the
                                                                                                                                                              this
                                                                             NEWLINEs within the string,
                                                      this within the brackets
                                                                                                                                    several lines and non-printable characters
                          or just a NEWLINE within
variable assignment will also show up.
                                                                                                                                                               is
                                                                                                                                                              а
                                                                                                        ) and they will show up that way when displayed.
                                                                                                                                                           long
                                                                                                                                                          string that
                                                                                                                                                            is made
                                                                               whether explicitly
                                                                                                                                                             þ
                                                                                                                                                             ٥f
                                                                                                                                    such
                                                                              given like
```

put into a raw string stays the way you wrote it-Raw strings do not treat the backslash as a special character at all. Every character you

```
#!/usr/bin/python3
('C:\\nowhere')
```

When the above code is executed, it produces the following result-

```
C:\nowhere
```

Now let us make use 앜 raw string. We would put expression in r'expression' as follows:

```
#!/usr/bin/python3
```

```
print (r'C:\\nowhere')
```

When the above code is executed, it produces the following result-

```
C:\\nowhere
```

## **Unicode String**

now. In Python 3, all strings are represented in Unicode. In Python 2 are stored internally as 8-bit ASCII, hence it is required to attach 'u' to make it Unicode. It is no longer necessary

## **Built-in String Methods**

Python includes the following built-in methods to manipulate strings-

6	И	4	ω	2	1	S. No.	
endswith(suffix, beg=0, end=len(string))	encode(encoding='UTF-8',errors='strict')  Returns encoded string version of string; on error, default is to raise a ValueError unless errors is given with 'ignore' or 'replace'.	<pre>decode(encoding='UTF-8',errors='strict')  Decodes the string using the codec registered for encoding. encoding defaults to the default string encoding.</pre>	<pre>count(str, beg= 0,end=len(string)) Counts how many times str occurs in string or in a substring of string if starting index beg and ending index end are given.</pre>	<b>center(width, fillchar)</b> Returns a string padded with <i>fillchar</i> with the original string centered to a total of <i>width</i> columns.	<b>capitalize()</b> Capitalizes first letter of string	Methods with Description	

7 9 9	Determines if string or a substring of string (if starting index beg and ending index end are given) ends with suffix; returns true if so and false otherwise.  expandtabs(tabsize=8)  Expands tabs in string to multiple spaces; defaults to 8 spaces per tab if tabsize not provided.  find(str, beg=0 end=len(string))  Determine if str occurs in string or in a substring of string if starting index beg and ending index end are given returns index if found and -1 otherwise.  index(str, beg=0, end=len(string))  Same as find(), but raises an exception if str not found.  isalnum()  isalnum()  Returns true if string has at least 1 character and all characters are alphanumeric and false otherwise.
	find(str, beg=0 end=len(string))  Determine if str occurs in string or in a substring of string if starting index beg and ending index end are given returns index if found and -1 otherwise.  index(str, beg=0, end=len(string))  Same as find(), but raises an exception if str not found.
10	east
11	<b>isalpha()</b> Returns true if string has at least 1 character and all characters are alphabetic and false otherwise.
12	<b>isdigit()</b> Returns true if the string contains only digits and false otherwise.
13	<b>islower()</b> Returns true if string has at least 1 cased character and all cased characters are in lowercase and false otherwise.
14	<b>isnumeric()</b> Returns true if a unicode string contains only numeric characters otherwise.

	23	22	נ	71	21	20		ŀ	10	18		17		C	15	Ļ	л
Returns a translation table to be used in translate function.	maketrans()	Removes all leading whitespace in string.	lstrip()	Converts all uppercase letters in string to lowercase.	lower()	Returns a space-padded string with the original string left-justified to a total of width columns.	ljust(width[, fillchar])	Returns the length of the string	len(string)	Merges (concatenates) the string representations of elements in sequence seq into a string, with separator string.	join(seq)	Returns true if string has at least one cased character and all cased characters are in uppercase and false otherwise.	isupper()	Returns true if string is properly "titlecased" and false otherwise.	istitle()	Returns true if string contains only whitespace characters and false otherwise.	isspace()

of substri	split(str=	rstrip() 30 Removes	rjust(width,[, fi 29 Returns a space-l of width columns	rindex( s 28 Same as i	rfind(str, 27 Same as f	replace(old, 26 Replaces all o if max given.	min(str) 25 Returns th	max(str) 24 Returns th
splitlines( num=string.count('\n'))	<pre>split(str="", num=string.count(str)) Splits string according to delimiter str (space if not provided) and returns list of substrings; split into at most num substrings if given.</pre>	rstrip() Removes all trailing whitespace of string.	<b>rjust(width,[, fillchar])</b> Returns a space-padded string with the original string right-justified to a total of width columns.	rindex( str, beg=0, end=len(string)) Same as index(), but search backwards in string.	rfind(str, beg=0,end=len(string)) Same as find(), but search backwards in string.	replace(old, new [, max])  Replaces all occurrences of old in string with new or at most max occurrences if max given.	<b>min(str)</b> Returns the min alphabetical character from the string str.	max(str) Returns the max alphabetical character from the string str.

40	39	38	37	36	35	34	<u> </u>
isdecimal()  Returns true if a unicode string contains only decimal characters and false otherwise.	zfill (width)  Returns original string leftpadded with zeros to a total of width characters; intended for numbers, zfill() retains any sign given (less one zero).	upper()  Converts lowercase letters in string to uppercase.	translate(table, deletechars="")  Translates string according to translation table str(256 chars), removing those in the del string.	title()  Returns "titlecased" version of string, that is, all words begin with uppercase and the rest are lowercase.	swapcase() Inverts case for all letters in string.	strip([chars])  Performs both lstrip() and rstrip() on string	Startswith(str, beg=0,end=len(string))  Determines if string or a substring of string (if starting index beg and ending index end are given) starts with substring str; returns true if so and false otherwise.

# String capitalize() Method

It returns a copy of the string with only its first character capitalized.

#### Syntax

```
str.capitalize()
```

## **Parameters**

Z

## **Return Value**

string

#### Example

```
print ("str.capitalize() :
                                                     #!/usr/bin/python3
                            str = "this
                         is string example....wow!!!"
ζ=
   str.capitalize())
```

#### Result

```
str.capitalize() :
 This
is
string example...wow!!!
```

## String center() Method

The method center() returns centered in a string of length width. Padding is done using the specified fillchar. Default filler is a space.

#### Syntax

```
str.center(width[,
fillchar])
```

## **Parameters**

- width This is the total width of the string.
- fillchar This is the filler character.

## **Return Value**

string with the character fillchar (default is a space). This method returns a string that is at least width characters wide, created by padding the

#### Example

The following example shows the usage of the center() method.

```
str = "this is string
                              #!/usr/bin/python3
example....wow!!!"
```

```
print
 ("str.center(40,
  а'
)
  ..
. =
  str.center(40,
  'a'))
```

#### Result

```
str.center(40,
 'a')
 ..
 aaaathis
  is
string example....wow!!!aaaa
```

## String count() Method

## **Description**

The **count()** method returns the number of occurrences of substring sub in the [start, end]. Optional arguments start and end are interpreted as in slice notation. range

#### Syntax

```
str.count(sub,
 start=
0,end=len(string))
```

## **Parameters**

- **sub** This is the substring to be searched.
- **start** Search starts from this index. First character starts from 0 index. By default search starts from 0 index.
- search ends at the last index. end - Search ends from this index. First character starts from 0 index. By default

## **Return Value**

Centered in a string of length width.

#### Example

```
print ("str.count('exam',
                                                  print ("str.count('i') :
                                                                                                str="this is string example....wow!!!"
                                                                                                                         #!/usr/bin/python3
                            sub='exam'
   10,
                                                  str.count(sub))
   40) :
_=
   str.count(sub, 10, 40))
```

#### Result

```
str.count('exam',
           str.count('i') :
4
            ω
 40)
 ..
```

# String decode() Method

## Description

defaults to the default string encoding. The **decode()** method decodes the string using the codec registered for encoding.

#### Syntax

```
Str.decode(encoding='UTF-8',errors='strict')
```

### **Parameters**

- please visit: Standard Encodings. encoding This is the encodings to be used. For a list of all encoding schemes
- for errors is 'strict', meaning that encoding errors raise a UnicodeError. Other possible values are 'ignore', 'replace', 'xmlcharrefreplace', 'backslashreplace' and errors - This may be given to set a different error handling scheme. The default any other name registered via codecs.register\_error()..

## **Return Value**

Decoded string.

#### Example

```
print
  print
                                        Str =
                                                         Str
                                                                           #!/usr/bin/python3
                                                           Ш
                                     Str.encode('base64','strict');
  "Decoded
                    "Encoded
                                                          "this
                                                        is string example....wow!!!";
String:
                  String:
                    +
   +
 Str.decode('base64','strict')
```

#### Result

```
Decoded String:
                          Encoded String:
  this
                          b'dGhpcyBpcyBzdHJpbmcgZXhhbXBsZS4uLi53b3chISE=
  is
string example....wow!!!
```

# String encode() Method

## **Description**

scheme. The **encode()** method returns an encoded version of the string. Default encoding is the current default string encoding. The errors may be given to set a different error handling

#### Syntax

```
str.encode(encoding='UTF-8',errors='strict')
```

### **Parameters**

- please visit: Standard Encodings. encoding -This is the encodings to be used. For a list of all encoding schemes
- for errors is 'strict', meaning that encoding errors raise a UnicodeError. Other possible values are 'ignore', 'replace', 'xmlcharrefreplace', 'backslashreplace' and errors - This may be given to set a different error handling scheme. any other name registered via codecs.register\_error(). UnicodeError. Other The default

## **Return Value**

Decoded string.

#### Example

```
print ("Encoded String:
                              Str=base64.b64encode(Str.encode('utf-8',errors='strict'))
                                                                                      import base64
                                                                                                                  #!/usr/bin/python3
                                                          "this is
                                                        string example....wow!!!"
        =
  ·
   Str)
```

#### Result

```
Encoded String:

```

# String endswith() Method

## **Description**

restricting the matching with the given indices start and end. It returns True if the string ends with the specified suffix, otherwise return False optionally

#### Syntax

```
str.endswith(suffix[,
start[,
end]])
```

## **Parameters**

- suffix -This could be a string or could also be a tuple of suffixes to look for.
- **start** The slice begins from here.

• end - The slice ends here.

## **Return Value**

TRUE if the string ends with the specified suffix, otherwise FALSE.

#### Example

```
print
                                                                        print
 print
                                                                                              print (Str.endswith(suffix))
                                                                                                                        suffix='!!'
                                                                                                                                                 Str='this is
                                                                                                                                                                        #!/usr/bin/python3
                                                 suffix='exam'
                                                                      (Str.endswith(suffix, 20))
(Str.endswith(suffix, 0,
                       (Str.endswith(suffix))
                                                                                                                                               string example....wow!!!'
19))
```

#### Result

```
True
         False
                  True
                           True
```

# String expandtabs() Method

## **Description**

are expanded using spaces, optionally using the given tabsize (default 8).. The expandtabs() method returns a copy of the string in which the tab characters ie. '\t'

#### Syntax

```
str.expandtabs(tabsize=8)
```

## **Parameters**

tabsize - This specifies the number of characters to be replaced for a tab character '\t'.

## **Return Value**

expanded using spaces. This method returns a copy of the string in which tab characters i.e., <u>-[</u> have been

#### Example

```
print
                                                              print
print ("Double exapanded tab: " +
                                                                                                                           #!/usr/bin/python3
                             ("Defualt exapanded tab: " +
                                                            ("Original string: " + str)
                                                                                         "this is\tstring example....wow!!!"
  str.expandtabs(16))
                              str.expandtabs())
```

#### Result

```
Original string: this is
   Double exapanded tab: this is
                                         Defualt exapanded tab:
                                    this is string example....wow!!!
                                                                            string example....wow!!!
string example....wow!!!
```

## String find() Method

## **Description**

if the starting index beg and ending index end are given. The find() method determines if the string str occurs in string, or in a substring of string

#### Syntax

```
str.find(str,
beg=0 end=len(string))
```

## **Parameters**

- **str** This specifies the string to be searched.
- **beg** This is the starting index, by default its 0
- end This is the ending index, by default its equal to the lenght of the string.

## **Return Value**

Index if found and -1 otherwise.

#### Example

```
print
                                                                                                                        str1 = "this is string example...wow!!!"
print (str1.find(str2, 40))
                                                                                                                                                         #!/usr/bin/python3
                                                                                             str2 = "exam";
                             (str1.find(str2, 10))
                                                            (str1.find(str2))
```

#### Result

15 15 占

## String index() Method

## **Description**

but raises an exception if sub is not found. The index() method determines if the string str occurs in string or in a substring of string, if the starting index beg and ending index end are given. This method is same as find(),

#### Syntax

```
str.index(str,
beg=0
end=len(string))
```

## **Parameters**

- str This specifies the string to be searched.
- beg This is the starting index, by default its 0.
- end This is the ending index, by default its equal to the length of the string.

## **Return Value**

Index if found otherwise raises an exception if str is not found.

#### Example

```
print
                                           print
 print
                                                                                     str1 = "this is string example....wow!!!"
                                                                   str2 =
                                                                                                           #!/usr/bin/python3
                    (str1.index(str2, 10))
                                           (str1.index(str2))
(str1.index(str2,
                                                                 "exam";
 40))
```

#### Result

15

```
ValueError: substring not found
                                                                                                                                                         15

# String isalnum() Method

## **Description**

The isalnum() method checks whether the string consists of alphanumeric characters.

#### Syntax

Following is the syntax for isalnum() method-

```
str.isa1num()
```

## **Parameters**

Z

## **Return Value**

at least one character, false otherwise. This method returns true if all the characters in the string are alphanumeric and there is

#### Example

The following example shows the usage of isalnum() method.

```
print
print (str.isalnum())
                                                                              #!/usr/bin/python3
                                      (str.isalnum())
                                                          "this2016"
                  is string example....wow!!!"
                                                         # No space
                                                           ij.
                                                         this string
```

When we run the above program, it produces the following result-

```
False
        True
```

# String isalpha() Method

## Description

The isalpha() method checks whether the string consists of alphabetic characters only.

#### Syntax

Following is the syntax for islpha() method-

```
str.isalpha()
```

### **Parameters**

 $\stackrel{\sf N}{\succ}$ 

## **Return Value**

least one character, false otherwise. This method returns true if all the characters in the string are alphabetic and there is at

#### Example

The following example shows the usage of isalpha() method

```
print
                                                                               #!/usr/bin/python3
print (str.isalpha())
                     "this
                                       (str.isalpha())
                                                           "this"; # No space
                     is
                 string example....wow!!!"
                                                             Qο
                                                           digit in this string
```

#### Result

```
False
         True
```

## String isdigit() Method

## **Description**

The method isdigit() checks whether the string consists of digits only.

#### Syntax

Following is the syntax for isdigit() method-

```
str.isdigit()
```

## **Parameters**

Z

## **Return Value**

character, false otherwise. This method returns true if all characters in the string are digits and there is at least one

#### Example

The following example shows the usage of isdigit() method.

```
print
 print
                                                                                 #!/usr/bin/python3
                       str =
                                                            "123456";
                   "this is string example....wow!!!"
                                          (str.isdigit())
(str.isdigit())
                                                                # Only digit in this string
```

#### Result

```
False
         True
```

# String islower() Method

## Description

are lowercase. The islower() method checks whether all the case-based characters (letters) of the string

#### Syntax

Following is the syntax for islower() method-

```
str.islower()
```

## **Parameters**

Z

## **Return Value**

least one cased character, false otherwise. This method returns true if all cased characters in the string are lowercase and there is at

#### Example

The following example shows the usage of islower() method.

```
print
                                       print
                                                                              #!/usr/bin/python3
                     str =
                                                           SIHT"
                   "this is string
                                      (str.islower())
(str.islower())
                                                         is string example....wow!!!"
                 example....wow!!!"
```

#### Result

```
True
        False
```

# String isnumeric() Method

## Description

This method is present only on unicode objects. The **isnumeric()** method checks whether the string consists of only numeric characters.

**Note:** Unlike Python 2, all strings are represented in Unicode in Python 3. Given below is an example illustrating it.

#### Syntax

Following is the syntax for isnumeric() method-

```
str.isnumeric()
```

## **Parameters**

Ν

## Return Value

This method returns true if all characters in the string are numeric, false otherwise.

#### Example

The following example shows the usage of isnumeric() method.

```
print
  str
                                str =
                                             #!/usr/bin/python3
               (str.isnumeric())
"23443434"
                                "this2016"
```

```
print
(str.isnumeric())
```

#### Result

```
True
         False
```

# String isspace() Method

## **Description**

The isspace() method checks whether the string consists of whitespace..

#### Syntax

Following is the syntax for isspace() method-

```
str.isspace()
```

### **Parameters**

Z

## **Return Value**

at least one character, false otherwise. This method returns true if there are only whitespace characters in the string and there is

#### Example

The following example shows the usage of isspace() method.

```
print
                      str =
                                          print (str.isspace())
                                                                    str =
                                                                                       #!/usr/bin/python3
(str.isspace())
                  "This is string example....wow!!!"
```

#### Result

```
False
         True
```

## String istitle() Method

## Description

non-casebased letters are uppercase and all other case-based characters are lowercase. The istitle() method checks whether all the case-based characters in the string following

#### Syntax

Following is the syntax for istitle() method-

```
str.istitle()
```

### **Parameters**

Z

## **Return Value**

This method returns true if the string is a titlecased string and there is at least one character, for example uppercase characters may only follow uncased characters and lowercase characters only cased ones. It returns false otherwise.

#### Example

The following example shows the usage of istitle() method.

```
print
                                           print
                       str =
                                                                                       #!/usr/bin/python3
                                                                "This Is String
(str.istitle())
                    "This is string example....wow!!!"
                                           (str.istitle())
                                                                 Example...Wow!!!"
```

#### Result

```
False
         True
```

# String isupper() Method

## Description

are uppercase. The isupper() method checks whether all the case-based characters (letters) of the string

#### Syntax

Following is the syntax for isupper() method-

```
str.isupper()
```

### **Parameters**

Z

## **Return Value**

is at least one cased character, false otherwise. This method returns true if all the cased characters in the string are uppercase and there

#### Example

The following example shows the usage of isupper() method

```
print
print
                                                                                #!/usr/bin/python3
                                       (str.isupper())
(str.isupper())
                 "THIS is string
                                                             "THIS IS STRING
                 example....wow!!!"
                                                           EXAMPLE....WOW!!!"
```

#### Result

```
False
```

## String join() Method

## **Description**

joined by str separator. The **join()** method returns a string in which the string elements of sequence have been

#### Syntax

Following is the syntax for join() method-

```
str.join(sequence)
```

### **Parameters**

sequence - This is a sequence of the elements to be joined.

## **Return Value**

This method returns a string, which is the concatenation of the strings in the sequence **seq**. The separator between elements is the string providing this method.

#### Example

The following example shows the usage of join() method.

```
seq =
print (s.join( seq ))
                                                                           #!/usr/bin/python3
                                                     -
                       ("a", "b", "c")
                        # This is sequence of strings.
```

#### Result

```
a-b-c
```

## String len() Method

## **Description**

The **len()** method returns the length of the string.

#### Syntax

Following is the syntax for len() method -

```
len( str
```

### **Parameters**

Z

## **Return Value**

This method returns the length of the string.

#### Example

The following example shows the usage of len() method.

```
print ("Length of
                 str =
                              #!/usr/bin/python3
                 "this
                 is
                string
   the
  string:
              example....wow!!!"
ς=
   len(str))
```

#### Result

Length of the string: 32

## String ljust() Method

## Description

done using the specified fillchar (default is a space). The original string is returned if width is less than len(s). The method ljust() returns the string left justified in a string of length width. Padding is

#### Syntax

Following is the syntax for ljust() method –

```
str.ljust(width[,
fillchar])
```

## **Parameters**

- width This is string length in total after padding.
- fillchar This is filler character, default is a space

## **Return Value**

This method returns the string left justified in a string of length width. Padding is done using the specified fillchar (default is a space). The original string is returned if width is less than len(s).

#### Example

The following example shows the usage of ljust() method.

```
#!/usr/bin/python3
print str.ljust(50,
                              "this is string example....wow!!!"
 -<u>*</u>
-<u>*</u>
```

#### Result

```
this is
  string
example....wow!!!************
```

## String lower() Method

## **Description**

been lowercased. The method lower() returns a copy of the string in which all case-based characters have

#### Syntax

Following is the syntax for lower() method –

```
str.lower()
```

## **Parameters**

Ν

## **Return Value**

lowercased. This method returns a copy of the string in which all case-based characters have been

#### Example

The following example shows the usage of lower() method.

```
print
                 str =
                                   #!/usr/bin/python3
                 SIHT"
(str.lower())
                 IS STRING
                EXAMPLE....WOW!!!"
```

#### Result

```
this is
string
example....wow!!!
```

## String Istrip() Method

## Description

The **Istrip()** method returns a copy of the string in which all chars have been stripped from the beginning of the string (default whitespace characters).

#### Syntax

Following is the syntax for lstrip() method-

```
str.lstrip([chars])
```

## **Parameters**

chars - You can supply what chars have to be trimmed.

## **Return Value**

This method returns a copy of the string in which all chars have been stripped from the beginning of the string (default whitespace characters).

#### Example

The following example shows the usage of Istrip() method.

```
print
                                                         print
                                                                                                                  #!/usr/bin/python3
                              str =
                         "*****this is string example....wow!!!****"
                                                         (str.lstrip())
(str.lstrip('*'))
                                                                                  this is string example....wow!!!"
```

#### Result

```
this
  this is
                    15
                  string
string example....wow!!!****
                  example....wow!!!
```

# String maketrans() Method

## **Description**

The **maketrans()** method returns a translation table that maps each character in the intabstring into the character at the same position in the outtab string. Then this table is passed to the translate() function.

Note: Both intab and outtab must have the same length.

#### Syntax

Following is the syntax for maketrans() method-

```
str.maketrans(intab, outtab]);
```

## **Parameters**

- intab This is the string having actual characters.
- outtab This is the string having corresponding mapping character.

## Return Value

This method returns a translate table to be used translate() function.

#### Example

The following example shows the usage of maketrans() method. Under this, every vowel in a string is replaced by its vowel position -

```
#!/usr/bin/python3
intab = "aeiou"
```

```
print (str.translate(trantab))
                                                   trantab = str.maketrans(intab, outtab)
                                                                                 outtab
                            "this is
                                                                                  П
                                                                               "12345"
                       string example....wow!!!"
```

#### Result

```
th3s
 38
str3ng
2x1mp12....w4w!!!
```

## String max() Method

## Description

The max() method returns the max alphabetical character from the string str.

#### Syntax

Following is the syntax for max() method-

```
max(str)
```

## **Parameters**

str - This is the string from which max alphabetical character needs to be returned.

## **Return Value**

This method returns the max alphabetical character from the string str.

#### Example

The following example shows the usage of max() method.

```
print
print ("Max
                                                                     str =
                                                                                           #!/usr/bin/python3
                                                                    "this
                                            ("Max character: " + max(str))
                         "this
character: "
                                                                  is a string example....really!!!"
                   is a string example....wow!!!"
 + max(str))
```

#### Result

```
Max character:
            Max character:
×
            <
```

## String min() Method

## Description

The **min()** method returns the min alphabetical character from the string str.

#### Syntax

Following is the syntax for min() method-

```
min(str)
```

## **Parameters**

str - This is the string from which min alphabetical character needs to be returned.

## **Return Value**

This method returns the max alphabetical character from the string str.

#### Example

The following example shows the usage of min() method.

```
print
                                   print
                  str =
                                                                        #!/usr/bin/python3
                                   ("Min character:
 ("Min character:
                   "TUTORIALSPOINT"
                                                      "www.tutorialspoint.com"
    =
                                  + min(str))
 +
min(str))
```

#### Result

```
Min character: A
                  Min
                 character:
```

# String replace() Method

## Description

The **replace()** method returns a copy of the string in which the occurrences of old have been replaced with new, optionally restricting the number of replacements to max.

#### Syntax

Following is the syntax for replace() method-

```
str.replace(old,
new[,
 max])
```

## **Parameters**

- old This is old substring to be replaced.
- **new** This is new substring, which would replace old substring.
- replaced. max - If this optional argument max is given, only the first count occurrences are

## **Return Value**

new. If the optional argument max is given, only the first count occurrences are replaced. This method returns a copy of the string with all occurrences of substring old replaced by

#### Example

The following example shows the usage of replace() method

```
print
                 print
                                                   #!/usr/bin/python3
                                   "this
(str.replace("is",
               (str.replace("is",
                                    1s
                                 string example....wow!!! this
"was",
                 "was"))
 3))
                                   is
                                 really string"
```

#### Result

```

## String rfind() Method

## Description

such index exists, optionally restricting the search to string[beg:end]. The **rfind()** method returns the last index where the substring str is found, or ᆣ ≕; no

#### Syntax

Following is the syntax for rfind() method-

```
str.rfind(str,
 beg=0
end=len(string))
```

## **Parameters**

- str This specifies the string to be searched.
- beg This is the starting index, by default its 0.
- end This is the ending index, by default its equal to the length of the string.

## **Return Value**

This method returns last index if found and -1 otherwise.

#### Example

The following example shows the usage of rfind() method.

```
print
                                                     print
                                                                          print
                                                                                            print
 print
                                    print

## String rindex() Method

## Description

exception if no such index exists, optionally restricting the search to string[beg:end]. The **rindex()** method returns the last index where the substring str is found, or raises an

#### Syntax

Following is the syntax for rindex() method-

```
str.rindex(str,
beg=0
  end=len(string))
```

## **Parameters**

str - This specifies the string to be searched.

- beg This is the starting index, by default its 0.
- len This is ending index, by default its equal to the length of the string.

## **Return Value**

This method returns last index if found otherwise raises an exception if str is not found.

#### Example

The following example shows the usage of rindex() method

```
print
                     print
                                                              str1 = "this is really a
                                                                                 #!/usr/bin/python3
                                            П
(str1.rindex(str2,10))
                     (str1.rindex(str2))
                                          "is"
                                                             string
                                                             example....wow!!!"
```

#### Result

```

# String rjust() Method

## Description

The **rjust()** method returns the string right justified in a string of length width. Padding is done using the specified fillchar (default is a space). The original string is returned if width is less than len(s).

#### **Syntax**

Following is the syntax for rjust() method-

```
str.rjust(width[,
fillchar])
```

## **Parameters**

- width This is the string length in total after padding.
- fillchar This is the filler character, default is a space.

## Return Value

This method returns the string right justified in a string of length width. Padding is done using the specified fillchar (default is a space). The original string is returned if the width is less than len(s).

#### Example

The following example shows the usage of rjust() method

```
print
                               #!/usr/bin/python3
                "this

# String rstrip() Method

## Description

The **rstrip()** method returns a copy of the string in which all chars have been stripped from the end of the string (default whitespace characters).

#### Syntax

Following is the syntax for rstrip() method-

```
str.rstrip([chars])
```

#### **Parameters**

**chars** - You can supply what chars have to be trimmed.

## **Return Value**

end of the string (default whitespace characters). This method returns a copy of the string in which all chars have been stripped from the

#### Example

The following example shows the usage of rstrip() method.

```
print
                                                            #!/usr/bin/python3
   str =
                      (str.rstrip())
  "****this is
                                          this is

```

## String split() Method

## **Description**

The **split()** method returns a list of all the words in the string, using str as the separator (splits on all whitespace if left unspecified), optionally limiting the number of splits to num.

#### Syntax

Following is the syntax for split() method-

```
str.split(str="", num=string.count(str)).
```

#### **Parameters**

- str This is any delimeter, by default it is space.
- num this is number of lines to be made

## **Return Value**

This method returns a list of lines.

#### Example

The following example shows the usage of split() method.

```
print
print
                                                                                 #!/usr/bin/python3
                  (str.split('i',1))
                                      (str.split( ))
(str.split('w'))
                                                              "this
                                                           is string example....wow!!!"
```

#### Result

```
['th',
['this is string example....',
                                       ['this'
                  s
                                    'is',
                  is string example...wow!!!']
                                    'string',
                                    'example....wow!!!']
[,iiii, ',o,
```

# String splitlines() Method

## Description

The **splitlines()** method returns a list with all the lines in string, optionally including the line breaks (if num is supplied and is true).

#### **Syntax**

Following is the syntax for splitlines() method-

```
str.splitlines( num=string.count('\n'))
```

#### **Parameters**

to be included in the lines **num** - This is any number, if present then it would be assumed that the line breaks need

## Return Value

This method returns true if found matching with the string otherwise false.

#### Example

The following example shows the usage of splitlines() method.

```
print
                                          #!/usr/bin/python3
                     "this
(str.splitlines( ))
                      is
                  \nstring example....\nwow!!!"
```

#### Result

```

  15
. -
  'string
 example....',
  [,ii;mom,
```

# String startswith() Method

## **Description**

The **startswith()** method checks whether the string starts with str, optionally restricting the matching with the given indices start and end.

#### Syntax

Following is the syntax for startswith() method-

```
str.startswith(str,
beg=0,end=len(string));
```

## **Parameters**

- **str** This is the string to be checked.
- beg This is the optional parameter to set start index of the matching boundary.
- end This is the optional parameter to set start index of the matching boundary.

## **Return Value**

This method returns true if found matching with the string otherwise false

#### Example

The following example shows the usage of startswith() method

```
print
 print
                     print
                                                          str =
                                                                             #!/usr/bin/python3
                                                          "this
                    (str.startswith( 'string',
                                    (str.startswith( 'this' ))
 (str.startswith(
                                                       is string example....wow!!!"
'this',
                    8
)
 4 ))
```

#### Result

# String translate() Method

## Description

The method translate() returns a copy of the string in which all the characters have been translated using table (constructed with the maketrans() function in the string module), optionally deleting all characters found in the string deletechars.

#### Syntax

Following is the syntax for translate() method-

```
str.translate(table[, deletechars]);
```

### **Parameters**

- a translation table. table - You can use the maketrans() helper function in the string module to create
- deletechars The list of characters to be removed from the source string

## **Return Value**

This method returns a translated copy of the string.

#### Example

The following example shows the usage of translate() method. Under this, every vowel in a string is replaced by its vowel position.

```
print
                                                                             outtab =
                                                                                                     intab =
                                                                                                                           from string import maketrans
                                                                                                                                                       #!/usr/bin/python3
                                                  trantab = maketrans(intab, outtab)
                          "this
(str.translate(trantab))
                                                                                                     "aeiou"
                                                                              "12345"
                       is string example....wow!!!";

# String upper() Method

## **Description**

been uppercased. The upper() method returns a copy of the string in which all case-based characters have

#### **Syntax**

Following is the syntax for upper() method –

```
str.upper()
```

### **Parameters**

Z

## Return Value

uppercased. This method returns a copy of the string in which all case-based characters have been

#### Example

The following example shows the usage of upper() method.

```
print
                        str = "this is string example....wow!!!"
                                                   #!/usr/bin/python3
("str.upper :
",str.upper())
```

#### Result

```
str.upper :
   SIHT
   SI
  STRING EXAMPLE....WOW!!!
```

## String zfill() Method

## **Description**

The **zfill()** method pads string on the left with zeros to fill width.

#### Syntax

Following is the syntax for zfill() method-

```
str.zfill(width)
```

#### **Parameters**

width - This is final width of the string. This is the width which we would get after filling

## **Return Value**

This method returns padded string

#### Example

The following example shows the usage of zfill() method.

```
print
                                                              #!/usr/bin/python3
print ("str.zfill
                                         "this
                    ("str.zfill
                                      is string example....wow!!!"
                    ",str.zfill(40))
",str.zfill(50))
```

#### Result

```
str.zfill:
                             str.zfill
    00000000this is string example....wow!!!
is string example....wow!!!
```

# String isdecimal() Method

## Description

This method are present only on unicode objects. The isdecimal() method checks whether the string consists of only decimal characters

**Note:** Unlike in Python 2, all strings are represented as Unicode in Python 3. Given Below is an example illustrating it.

#### Syntax

Following is the syntax for isdecimal() method-

```
str.isdecimal()
```

#### **Parameters**

Z

## **Return Value**

This method returns true if all the characters in the string are decimal, false otherwise.

#### Example

The following example shows the usage of isdecimal() method.

```
str =
print (str.isdecimal())
                                         print (str.isdecimal())
                                                              str = "this2016"
                                                                                 #!/usr/bin/python3
                      "23443434"
```

#### Result

True False

# 11. Python 3 – Lists

assigned a number - its position or index. The first index is zero, the second index is one, and so forth. The most basic data structure in Python is the sequence. Each element of a sequence is

Python has six built-in types of sequences, but the most common ones are lists and tuples, which we would see in this tutorial.

indexing, slicing, adding, multiplying, and checking for membership. In addition, Python smallest elements. has built-in functions for finding the length of a sequence and for finding its largest and There are certain things you can do with all the sequence types. These operations include

## **Python Lists**

is that the items in a list need not be of the same type. of comma-separated values (items) between square brackets. Important thing about a list The list is the most versatile datatype available in Python, which can be written as а list

Creating a list is as simple as putting different comma-separated values between square brackets. For example-

```
list2 = [1, 2, 3, 4, 5];
                                           list1
= ["a", "b", "c", "d"];
                                          ['physics',
                                          'chemistry',
                                          1997,
                                          2000];
```

so on. Similar to string indices, list indices start at 0, and lists can be sliced, concatenated and

# **Accessing Values in Lists**

to obtain value available at that index. For example To access values in lists, use the square brackets for slicing along with the index or indices

```
print ("list1[0]: ", list1[0])
 print ("list2[1:5]:
                                         list2 = [1, 2, 3, 4,
                                                               list1 = ['physics',
                                                                                    #!/usr/bin/python3
ς=
                                                              'chemistry', 1997,
                                         5, 6,
 list2[1:5])
                                           7 ]
                                                                 2000]
```

When the above code is executed, it produces the following result

```
list2[1:5]:
          list1[0]:
          physics
[2,
ω
4
5]
```

## **Updating Lists**

You can update single or multiple elements of lists by giving the slice on the left-hand side of the assignment operator, and you can add to elements in a list with the append() method. For example-

```
print ("Value available at index 2 : ", list[2])
   print ("New value available
                                                                      list = ['physics', 'chemistry', 1997,
                           list[2] = 2001
                                                                                               #!/usr/bin/python3
     at index
     2
                                                                         2000]
    ••
ς=
    list[2])
```

Note: The append() method is discussed in the subsequent section.

When the above code is executed, it produces the following result -

```
1997
2001
                                     Value
            New value
                                     available at index
             available
             at
             index
                                     2
             2
```

# **Delete List Elements**

which items to delete. For example-To remove a list element, you can use either the **del** statement if you know exactly which element(s) you are deleting. You can use the remove() method if you do not know exactly

```
print ("After deleting value
                                                      list = ['physics', 'chemistry', 1997,
                                        print (list)
                                                                          #!/usr/bin/python3
                      del list[2]
      at
       index
                                                         2000]
       2
     ••
. . =
      list)
```

When the above code is executed, it produces the following result-

```
['physics',
                        After deleting value at index 2 :
remove()
                                              'chemistry', 1997, 2000]
 method is
 discussed
in subsequent section.
                       ['physics',
                         'chemistry',
                          2000]
```

# Basic List Operations

repetition here too, except that the result is a new list, not a string. Lists respond to the + and \* operators much like strings; they mean concatenation and

prior chapter. In fact, lists respond to all of the general sequence operations we used on strings in the

Python Expression	Results	Description
len([1, 2, 3])	8	Length
[1, 2, 3] + [4, 5, 6]	[1, 2, 3, 4, 5, 6]	Concatenation
['Hi!'] * 4	[יווו', יווו', יווו', יווו']	Repetition
3 in [1, 2, 3]	True	Membership
for x in [1,2,3] : print (x,end=' 123')	123	Iteration

# Indexing, Slicing and Matrixes

Since lists are sequences, indexing and slicing work the same way for lists as they do for strings.

Assuming the following input-

Python Expression	Results	Description
L[2]	'Python'	Offsets start at zero
니-2]	'Java'	Negative: count from the right
L[1:]	['Java', 'Python']	Slicing fetches sections

# **Built-in List Functions & Methods**

Python includes the following list functions-

	1	NS
No longer available in Python 3.	cmp(list1, list2)	SN Function with Description

5 C <b>=</b>	4 <b></b>	ω 2 3	2
list(seq) Converts a tuple into list.	<b>min(list)</b> Returns item from the list with min value.	max(list) Returns item from the list with max value.	<b>len(list)</b> Gives the total length of the list.

Let us understand the use of these functions.

## List len() Method

## Description

The **len()** method returns the number of elements in the list.

#### **Syntax**

Following is the syntax for len() method-

```
len(list)
```

## **Parameters**

list - This is a list for which, number of elements are to be counted.

## **Return Value**

This method returns the number of elements in the list.

#### Example

The following example shows the usage of len() method.

```
print (len(list2))
                                list2=list(range(5)) #creates list of numbers between 0-4
                                                                 print (len(list1))
                                                                                                 list1 = ['physics',
                                                                                                                                   #!/usr/bin/python3
                                                                                                 'chemistry', 'maths']
```

When we run above program, it produces following result-

σω

List max() Method

## Description

The max() method returns the elements from the list with maximum value

#### Syntax

Following is the syntax for max() method-

max(list)

### **Parameters**

list - This is a list from which max valued element are to be returned.

## **Return Value**

This method returns the elements from the list with maximum value.

#### Example

The following example shows the usage of max() method.

```
print ("Max value element :
                        print ("Max value element :
                                                   list1,
                                                                         #!/usr/bin/python3
                                               list2 = ['C++','Java',
                     ", max(list1))
", max(list2))
                                                'Python'], [456,
                                                  700, 200]
```

When we run above program, it produces following result-

```
Max value element :
                     Max value element :
  700
                     Python
```

## List min() Method

## **Description**

The method min() returns the elements from the list with minimum value.

#### Syntax

Following is the syntax for min() method-

```
min(list)
```

#### **Parameters**

list - This is a list from which min valued element is to be returned.

## **Return Value**

This method returns the elements from the list with minimum value.

#### Example

```
print
                                         list1, list2 = ['C++','Java',
   print ("min value element :
                                                               #!/usr/bin/python3
                                                                                   The following example shows
                       ("min value element :
ς=
                                                                                  the usage
                                        'Python'], [456,
                       min(list1))
  min(list2))
                                                                                   ٥f
                                                                                    min()
                                                                                    method.
                                          700, 200]
```

When we run above program, it produces following result-

```
min value element :
              value
             element
200
              7
```

## List list() Method

## **Description**

a given tuple into list. The list() method takes sequence types and converts them to lists. This is used to convert

bracket. This function also converts characters in a string into a list. can not be changed and tuple elements are put between parentheses instead of square Note: Tuple are very similar to lists with only difference that element values of a tuple

#### Syntax

Following is the syntax for list() method-

```
list( seq
   \overline{\phantom{a}}
```

#### **Parameters**

seq - This is a tuple or string to be converted into list.

## **Return Value**

This method returns the list.

#### Example

The following example shows the usage of list() method.

```
print ("List elements :
                                             str="Hello World"
                                                                   print ("List elements
                                                                                       list1 = list(aTuple)
                                                                                                           aTuple = (123, 'C++',
                                                                                                                                #!/usr/bin/python3
                        list2=list(str)
                                                                                                            'Java', 'Python')
ζ=
                                                                   list1)
     list2)
```

When we run above program, it produces following result-

```
List
List elements :
           elements
, H.]
           [123,

Python includes the following list methods-

NS	Methods with Description
1	list.append(obj)
	Appends object obj to list
2	list.count(obj)
	Returns count of how many times obj occurs in list
3	list.extend(seq)
	Appends the contents of seq to list
4	list.index(obj)
	Returns the lowest index in list that obj appears
5	list.insert(index, obj)
	Inserts object obj into list at offset index

9	8	7	6
list.sort([func]) Sorts objects of list, use compare func if given	list.reverse()  Reverses objects of list in place	<b>list.remove(obj)</b> Removes object obj from list	list.pop(obj=list[-1]) Removes and returns last object or obj from list

# List append() Method

## **Description**

The append() method appends a passed obj into the existing list.

#### Syntax

Following is the syntax for append() method-

```
list.append(obj)
```

## **Parameters**

**obj** - This is the object to be appended in the list.

## **Return Value**

This method does not return any value but updates existing list.

#### Example

The following example shows the usage of append() method.

```
print ("updated list : ", list1)
                                list1.append('C#')
                                                             list1 = ['C++', 'Java', 'Python']
                                                                                               #!/usr/bin/python3
```

When we run the above program, it produces the following result-

```
updated list :
['C++', 'Java', 'Python', 'C#']
```

## List count() Method

## Description

The count() method returns count of how many times obj occurs in list.

#### Syntax

Following is the syntax for count() method-

```
list.count(obj)
```

## **Parameters**

**obj** - This is the object to be counted in the list.

## **Return Value**

This method returns count of how many times obj occurs in list.

#### Example

The following example shows the usage of count() method

```
print
                 print ("Count for 123 :
                                                    #!/usr/bin/python3
("Count for zara :
                                   'xyz',
                                   'zara',
              ς=
                   aList.count(123))
aList.count('zara'))
                                   'abc', 123];
```

When we run the above program, it produces the following result-

```
Count
Count for zara :
           for
           123 :
           2
```

# List extend() Method

## Description

The extend() method appends the contents of seq to list.

#### Syntax

Following is the syntax for extend() method-

```
list.extend(seq)
```

#### **Parameters**

seq - This is the list of elements

## **Return Value**

This method does not return any value but adds the content to an existing list.

#### Example

The following example shows the usage of extend() method

```
list2=list(range(5))
                                                                                               list1 = ['physics',
                                                                                                                              #!/usr/bin/python3
                               list1.extend('Extended List :', list2)
(list1)
                                                                                            'chemistry', 'maths']
                                                                   #creates list of numbers between 0-4
```

When we run the above program, it produces the following result-

```
Extended List
['physics',
'chemistry',
'maths',
ô
1,
2
 ω
 4
```

## List index() Method

### **Description**

The **index()** method returns the lowest index in list that obj appears.

#### Syntax

Following is the syntax for index() method-

```
list.index(obj)
```

### **Parameters**

**obj** - This is the object to be find out.

## **Return Value**

that the value is not found. This method returns index of the found object otherwise raises an exception indicating

#### Example

The following example shows the usage of index() method.

```
print
                                                                   list1 = ['physics',
                                                                                                      #!/usr/bin/python3
('Index of C#', list1.index('C#'))
                                 ('Index of chemistry', list1.index('chemistry'))
                                                                   'chemistry', 'maths']
```

When we run the above program, it produces the following result-

```
ValueError: 'C#' is not in list
                                                                                                         Traceback (most recent call last):
                                                                 File "test.py",
                              print ('Index of C#', list1.index('C#'))
                                                                                                                                            of chemistry 1
                                                                 line 3,
```

## List insert() Method

## **Description**

The insert() method inserts object obj into list at offset index.

#### Syntax

Following is the syntax for insert() method-

```
list.insert(index, obj)
```

### **Parameters**

- index This is the Index where the object obj need to be inserted
- obj This is the Object to be inserted into the given list

## **Return Value**

This method does not return any value but it inserts the given element at the given index.

#### Example

The following example shows the usage of insert() method.

```
list1 = ['physics', 'chemistry',
                                                                                      #!/usr/bin/python3
                          list1.insert(1, 'Biology')
('Final list :
                                                        'maths']
```

When we run the above program, it produces the following result-

```
Final
list
..
['physics',
'Biology',
'chemistry',
'maths']
```

## List pop() Method

## Description

The pop() method removes and returns last object or obj from the list.

#### **Syntax**

Following is the syntax for pop() method-

```
list.pop(obj=list[-1])
```

## **Parameters**

obj - This is an optional parameter, index of the object to be removed from the list.

## **Return Value**

This method returns the removed object from the list.

#### Example

The following example shows the usage of pop() method.

```
print ("list now : ",
                                        print ("list now :
                                                                              list1 = ['physics',
                                                                                                   #!/usr/bin/python3
                    list1.pop(1)
                                                            list1.pop()
                                                                              'Biology',
  list1)
                                        list1)
                                                                               'chemistry',
                                                                               'maths']
```

When we run the above program, it produces the following result-

```
list now :
                  list now :
['physics',
               ['physics',
'chemistry']
                'Biology',
                 'chemistry']
```

# List remove() Method

#### **Parameters**

obj - This is the object to be removed from the list.

## **Return Value**

This method does not return any value but removes the given object from the list.

#### Example

The following example shows the usage of remove() method.

```
print ("list now : ", list1)
                                                               print ("list now : ", list1)
                                list1.remove('maths')
                                                                                              list1.remove('Biology')
                                                                                                                                                               #!/usr/bin/python3
                                                                                                                              ['physics', 'Biology',
                                                                                                                               'chemistry',
```

When we run the above program, it produces the following result-

```
list now :
                now :
['physics',
             ['physics',
'chemistry']
             'chemistry',
                'maths']
```

# List reverse() Method

## Description

The reverse() method reverses objects of list in place.

#### Syntax

Following is the syntax for reverse() method-

```
list.reverse()
```

## **Parameters**

Z

## **Return Value**

This method does not return any value but reverse the given object from the list.

#### Example

The following example shows the usage of reverse() method.

```
#!/usr/bin/python3
                                       list1 = ['physics', 'Biology',
                       list1.reverse()
     ("list now :
ς=
     list1)
                                          'chemistry',
                                          'maths']
```

When we run above program, it produces following result-

```
list
 now :
['maths',
'chemistry',
'Biology', 'physics']
```

## List sort() Method

## Description

The **sort()** method sorts objects of list, use compare function if given.

#### Syntax

Following is the syntax for sort() method-

```
list.sort([func])
```

## **Parameters**

Ζ

## **Return Value**

This method does not return any value but reverses the given object from the list.

#### Example

The following example shows the usage of sort() method.

```
print ("list now : ", list1)
                      list1.sort()
                                           list1 = ['physics',
                                                                 #!/usr/bin/python3
                                          'Biology',
                                            'chemistry',
                                             'maths']
```

When we run the above program, it produces the following result-

```
list now :
['Biology',
'chemistry', 'maths', 'physics']
```

# 12. Python 3 — Tuples

unlike lists. Tuples use parentheses, whereas lists use square brackets. A tuple is a sequence of immutable Python objects. Tuples are sequences, just like lists. The main difference between the tuples and the lists is that the tuples cannot be changed

Creating a tuple is as simple as putting different comma-separated values. Optionally, you can put these comma-separated values between parentheses also. For example-

```
"a", "b", "c", "d"
                            (1, 2, 3, 4, 5)
                                                            ('physics', 'chemistry', 1997, 2000)
```

The empty tuple is written as two parentheses containing nothing.

```
tup1 = ();
```

is only one value. To write a tuple containing a single value you have to include a comma, even though there

```
tup1 = (50,)
```

on. Like string indices, tuple indices start at 0, and they can be sliced, concatenated, and so

# **Accessing Values in Tuples**

To access values in tuple, use the square brackets for slicing along with the index or indices to obtain the value available at that index. For example-

```
print ("tup2[1:5]: ", tup2[1:5])
                                print ("tup1[0]: ", tup1[0])
                                                                tup2 = (1, 2, 3, 4, 5, 6, 7)
                                                                                                                                   #!/usr/bin/python3
                                                                                               ('physics', 'chemistry', 1997,
                                                                                                     2000)
```

When the above code is executed, it produces the following result-

```
tup2[1:5]:
         tup1[0]:
          physics
[2,
ω
4
5
```

## **Updating Tuples**

Tuples are immutable, which means you cannot update or change the values of tuple elements. You are able to take portions of the existing tuples to create new tuples as the following example demonstrates.

```
#
                                                                                                                                                                                                           tup1
print (tup3)
                                                                                                                                                                                 tup2 = ('abc', 'xyz')
                                                                                                                                                                                                                                                           #!/usr/bin/python3
                          tup3 = tup1 + tup2
                                                    So
                                                                                                      tup1[0] = 100;
                                                                                                                              Following action is not valid for tuples
                                                    let's create a
                                                                                                                                                                                                           (12, 34.56)
                                                   new tuple as follows
```

When the above code is executed, it produces the following result-

```
34.56,
'abc',
 'xyz')
```

# Delete Tuple Elements

Removing individual tuple elements is not possible. There is, of course, nothing wrong with putting together another tuple with the undesired elements discarded.

To explicitly remove an entire tuple, just use the **del** statement. For example-

```
print tup
                              print "After deleting tup :
                                                          del tup;
                                                                                          print (tup)
                                                                                                                       tup = ('physics', 'chemistry', 1997, 2000);
                                                                                                                                                       #!/usr/bin/python3
```

This produces the following result

Note: An exception is raised. This is because after del tup, tuple does not exist any more

```
Traceback (most recent call last):

```

NameError: name 'tup' is not defined

# **Basic Tuples Operations**

Tuples respond to the  $\pm$  and  $\pm$  operators much like strings; they mean concatenation and repetition here too, except that the result is a new tuple, not a string.

In fact, tuples respond to all of the general sequence operations we used on strings in the previous chapter.

Python Expression	Results	Description
len((1, 2, 3))	3	Length
(1, 2, 3) + (4, 5, 6)	(1, 2, 3, 4, 5, 6)	Concatenation
('Hi!',) * 4	('Hi!', 'Hi!', 'Hi!', 'Hi!')	Repetition
3 in (1, 2, 3)	True	Membership
for x in (1,2,3) : print (x, end=' 1 2 3 ')	123	Iteration

# Indexing, Slicing, and Matrixes

Since tuples are sequences, indexing and slicing work the same way for tuples as they do for strings, assuming the following input-

T=('C++', 'Java', 'Python')

Python Expression	Results	Description
Τ[2]	'Python'	Offsets start at zero
Τ[-2]	'Java'	Negative: count from the right
Τ[1:]	('Java', 'Python')	Slicing fetches sections

# No Enclosing Delimiters

No enclosing Delimiters is any set of multiple objects, comma-separated, written without identifying symbols, i.e., brackets for lists, parentheses for tuples, etc., default to tuples, as indicated in these short examples.

# **Built-in Tuple Functions**

Python includes the following tuple functions-

SN	Function with Description
1	cmp(tuple1, tuple2)  No longer available in Python 3.
2	len(tuple) Gives the total length of the tuple.
ω	max(tuple) Returns item from the tuple with max value.
4	min(tuple) Returns item from the tuple with min value.
Л	tuple(seq) Converts a list into tuple.

## Tuple len() Method

## **Description**

The len() method returns the number of elements in the tuple.

#### Syntax

Following is the syntax for len() method-

len(tuple)

## **Parameters**

tuple - This is a tuple for which number of elements to be counted.

## **Return Value**

This method returns the number of elements in the tuple.

#### Example

The following example shows the usage of len() method.

```
print ("First tuple length : ", len(tuple1))
                                                                         tuple1, tuple2 = (123, 'xyz', 'zara'), (456,
                                                                                                                #!/usr/bin/python3
("Second tuple length : ",
len(tuple2))
```

When we run above program, it produces following result-

```
Second tuple length :
                      First tuple length :
   2
```

## Tuple max() Method

## **Description**

The max() method returns the elements from the tuple with maximum value.

#### Syntax

Following is the syntax for max() method-

```
max(tuple)
```

### **Parameters**

tuple - This is a tuple from which max valued element to be returned.

## **Return Value**

This method returns the elements from the tuple with maximum value

#### Example

The following example shows the usage of max() method

```
print ("Max value element
                  print ("Max value element
                                     tuple1, tuple2 = ('maths',
                                                        #!/usr/bin/python3
                   ••
  ••
                                     'che',
                  ", max(tuple1))
max(tuple2))
                                     'phy',
                                     'bio'), (456,
                                     700,
                                       200)
```

When we run the above program, it produces the following result-

```
Max value element :
                  Max value element
                phy
700
```

## Tuple min() Method

### **Description**

The **min()** method returns the elements from the tuple with minimum value.

#### Syntax

Following is the syntax for min() method-

```
min(tuple)
```

#### **Parameters**

tuple - This is a tuple from which min valued element is to be returned.

## Return Value

This method returns the elements from the tuple with minimum value.

#### Example

The following example shows the usage of min() method.

```
print ("min value element :
                          print ("min value element
                                                 tuple1, tuple2 = ('maths',
                                                                            #!/usr/bin/python3
                                                 'che', 'phy', 'bio'), (456,
                       ", min(tuple1))
", min(tuple2))
                                                     , 997
                                                      200)
```

When we run the above program, it produces the following result-

```
min value element :
                    min value element :
                    bio
 200
```

# Tuple tuple() Method

## **Description**

The tuple() method converts a list of items into tuples.

#### Syntax

Following is the syntax for tuple() method-

```
tuple( seq )
```

## **Parameters**

**seq** - This is a tuple to be converted into tuple.

## **Return Value**

This method returns the tuple.

#### Example

The following example shows the usage of tuple() method.

```
print ("tuple elements : ", tuple1)
                                  tuple1=tuple(list1)
                                                                  list1= ['maths', 'che', 'phy', 'bio']
                                                                                                       #!/usr/bin/python3
```

When we run the above program, it produces the following result-

```
tuple elements
('maths', 'che', 'phy',
'bio')
```

# 13. Python 3 — Dictionary

written with just two curly braces, like this: {}. Each key is separated from its value by a colon (:), the items are separated by commas, and the whole thing is enclosed in curly braces. An empty dictionary without any items is

can be of any type, but the keys must be of an immutable data type such as strings, numbers, or tuples. Keys are unique within a dictionary while values may not be. The values of a dictionary

# **Accessing Values in Dictionary**

key to obtain its value. Following is a simple example. To access dictionary elements, you can use the familiar square brackets along with the

```
print ("dict['Age']: ", dict['Age'])
                                print ("dict['Name']: ", dict['Name'])
                                                                                                                                               #!/usr/bin/python3
                                                                                         {'Name': 'Zara',
                                                                                         'Age':
                                                                                         7,
                                                                                          'Class': 'First'}
```

When the above code is executed, it produces the following result-

```
dict['Name']:
dict['Age']:
```

get an error as follows-If we attempt to access a data item with a key, which is not a part of the dictionary, we

```
print "dict['Alice']: ",
                                                                                                    #!/usr/bin/python3
                                                     dict =
                                                   {'Name': 'Zara',
                                                'Age': 7,
dict['Alice']
                                                    'Class': 'First'};
```

When the above code is executed, it produces the following result-

```
Traceback (most recent call last):
KeyError:
                                                                                        dict['Zara']:
                                          File "test.py",
                      print "dict['Alice']:
'Alice'
                                          line 4, in <module>
                  ζ=
                     dict['Alice'];
```

# **Updating Dictionary**

You can update a dictionary by adding a new entry or a key-value pair, modifying an existing entry, or deleting an existing entry as shown in a simple example given below.

```
print ("dict['Age']: ", dict['Age'])
                                                                                      dict['School'] = "DPS School" # Add new entry
                                                                                                                                                                                     dict = {'Name': 'Zara', 'Age': 7, 'Class': 'First'}
                                                                                                                                                                                                                                                                                      #!/usr/bin/python3
print ("dict['School']:
                                                                                                                                         dict['Age'] = 8; # update existing entry
", dict['School'])
```

When the above code is executed, it produces the following result-

```
dict['School']:
              dict['Age']:
              œ
DPS
School
```

# **Delete Dictionary Elements**

dictionary. You can also delete entire dictionary in a single operation. You can either remove individual dictionary elements or clear the entire contents 으

example-To explicitly remove an entire dictionary, just use the **del** statement. Following is a simple

```
print ("dict['School']: ", dict['School'])
                                    print ("dict['Age']: ",
                                                                                                                                                                                                                                                                                                                                           #!/usr/bin/python3
                                                                                                                    del dict
                                                                                                                                                      dict.clear()
                                                                                                                                                                                          del dict['Name'] # remove entry with key 'Name'
                                                                                                                                                                                                                                                                  {'Name': 'Zara', 'Age': 7,
                                                                                                                                                    # remove all entries in dict
                                                                                                                   # delete entire dictionary
                                       dict['Age'])
                                                                                                                                                                                                                                                                    'Class': 'First'}
```

This produces the following result.

anymore. Note: An exception is raised because after del dict, the dictionary does not exist

```
dict['Age']:
                    Traceback (most recent
File "test.py",
 line
8, in <module>
                      call last):
```

```
TypeError:
                 print "dict['Age']:
 'type'
object is unsubscriptable
                =
                  dict['Age'];
```

Note: The del() method is discussed in subsequent section.

# Properties of Dictionary Keys

standard objects or user-defined objects. However, same is not true for the keys. Dictionary values have no restrictions. They can be any arbitrary Python object, either

There are two important points to remember about dictionary keys-

(a) More than one entry per key is not allowed. This means no duplicate key is allowed. When duplicate keys are encountered during assignment, the last assignment wins. For

```
print ("dict['Name']: ", dict['Name'])
                                                                      dict =
                                                                                                                                   #!/usr/bin/python3
                                                                   {'Name': 'Zara', 'Age': 7, 'Name':
                                                                      'Manni'}
```

When the above code is executed, it produces the following result-

```
dict['Name']:
 Manni
```

(b) Keys must be immutable. This filed by you can use surrise, have a simple example-dictionary keys but something like ['key'] is not allowed. Following is a simple exampleas

```
print ("dict['Name']: ", dict['Name'])
                                                                                                                        #!/usr/bin/python3
                                                         {['Name']: 'Zara',
                                                            'Age': 7}
```

When the above code is executed, it produces the following result-

```
TypeError:
                                                                                      Traceback (most recent call last):
                                                       File "test.py", line
                              dict =
list objects are unhashable
                         {['Name']: 'Zara',
                                                        3, in <module>
                           'Age': 7}
```

# **Built-in Dictionary Functions & Methods**

Python includes the following dictionary functions-

# Dictionary len() Method

would be equal to the number of items in the dictionary. DescriptionThe method len() gives the total length of the dictionary. This

#### Syntax

Following is the syntax for len() method-

len(dict)

## **Parameters**

dict - This is the dictionary, whose length needs to be calculated.

## **Return Value**

This method returns the length.

#### Example

The following example shows the usage of len() method.

#!/usr/bin/python3

```
print
("Length
           : %d"
          'Manni',
% len (dict))
          'Age': 7,
            Class
           ..-
           'First'}
```

When we run the above program, it produces the following result-

```
Length
ω
```

### Dictionary str() Method

### Description

The method **str()** produces a printable string representation of a dictionary.

#### Syntax

Following is the syntax for str() method –

```
str(dict)
```

### **Parameters**

dict - This is the dictionary.

### Return Value

This method returns string representation.

### Example

The following example shows the usage of str() method.

```
print
                     dict =
                                      #!/usr/bin/python3
("Equivalent String : %s"
                  {'Name': 'Manni',
                   'Age':
                   7,
 % str (dict))
                     'Class': 'First'}
```

When we run the above program, it produces the following result-

```
Equivalent
String
{'Name':
'Manni',
'Age':
7,
'Class':
'First'}
```

## Dictionary type() Method

### **Description**

The method **type()** returns the type of the passed variable. If passed variable is dictionary then it would return a dictionary type.

#### **Syntax**

Following is the syntax for type() method-

```
type(dict)
```

### **Parameters**

dict - This is the dictionary.

### **Return Value**

This method returns the type of the passed variable.

### Example

The following example shows the usage of type() method.

```
print ("Variable Type : %s" %
                             dict = {'Name': 'Manni', 'Age': 7, 'Class':
                                                          #!/usr/bin/python3
type (dict))
                              'First'}
```

When we run the above program, it produces the following result-

```
Variable Type : <type 'dict'>
```

Python includes the following dictionary methods-

Adds dictio	9 dict.update(dict2)	8 <b>dict.setde</b> Similar to 9	7 dict.keys() Returns list	6 dict.items() Returns a list	5 <b>dict.has_key(key)</b> Removed, use the <b>ir</b>
dict.values()	<b>dict.update(dict2)</b> Adds dictionary <i>dict2</i> 's key-values pairs to <i>dict</i> .	<pre>dict.setdefault(key, default=None) Similar to get(), but will set dict[key]=default if key is not already in dict.</pre>	dict.keys() Returns list of dictionary dict's keys.	<b>dict.items()</b> Returns a list of <i>dict</i> 's (key, value) tuple pairs.	dict.has_key(key) Removed, use the in operation instead.

# Dictionary clear() Method

### **Description**

The method clear() removes all items from the dictionary.

#### Syntax

Following is the syntax for clear() method-

```
dict.clear()
```

### **Parameters**

Z

### **Return Value**

This method does not return any value.

### Example

The following example shows the usage of clear() method.

#!/usr/bin/python3

```
print ("End Len :
                                        print ("Start Len : %d" % len(dict))
                      dict.clear()
                                                            {'Name': 'Zara',
  %d"
  %
                                                            'Age': 7}
len(dict))
```

When we run the above program, it produces the following result-

```
End Len : 0
               Start Len
                2
```

# Dictionary copy() Method

### **Description**

The method copy() returns a shallow copy of the dictionary.

#### Syntax

Following is the syntax for copy() method-

```
dict.copy()
```

### **Parameters**

Z

### **Return Value**

This method returns a shallow copy of the dictionary.

### Example

The following example shows the usage of copy() method.

```
dict2 = dict1.copy()
                                                               dict1 = {'Name': 'Manni', 'Age': 7,
                                                                                                 #!/usr/bin/python3
("New Dictionary : ",dict2)
                                                                    'Class': 'First'}
```

When we run the above program, it produces following result-

```
New dictionary
 ..
{'Name': 'Manni',
'Age': 7,
 'Class': 'First'}
```

# Dictionary fromkeys() Method

### Description

value. The method fromkeys() creates a new dictionary with keys from seq and values set to

#### Syntax

Following is the syntax for fromkeys() method-

```
dict.fromkeys(seq[,
 value]))
```

### **Parameters**

- seq This is the list of values which would be used for dictionary keys preparation.
- value This is optional, if provided then value would be set to this value

### **Return Value**

This method returns the list.

### Example

The following example shows the usage of fromkeys() method

```
print ("New Dictionary : %s" %
                      dict
                                       print ("New Dictionary : %s" %
                                                                                    seq =
                                                              dict = dict.fromkeys(seq)
                                                                                                        #!/usr/bin/python3
                                                                                  ('name',
                     dict.fromkeys(seq,
                                                                                 'age',
                                                                                    'sex')
                      10)
str(dict))
                                          str(dict))
```

When we run the above program, it produces the following result-

```
New Dictionary
                   New Dictionary
  ••
{'age':
                   {'age': None, 'name': None, 'sex': None}
 10,
  'name':
 10,
  'sex': 10}
```

### Dictionary get() Method

### **Description**

The method **get()** returns a value for the given key. If the key is not available then returns default value None.

#### Syntax

Following is the syntax for get() method-

```
dict.get(key, default=None)
```

### **Parameters**

- key This is the Key to be searched in the dictionary.
- default This is the Value to be returned in case key does not exist.

### **Return Value**

default value as None. This method returns a value for the given key. If the key is not available, then returns

### Example

The following example shows the usage of get() method.

```
print
                      print ("Value : %s" %
                                           dict = {'Name': 'Zara', 'Age': 27}
                                                                #!/usr/bin/python3
 ("Value :
    %s"
    %
                     dict.get('Age'))
dict.get('Sex', "NA"))
```

When we run the above program, it produces the following result-

```
Value
Value : NA
         ••
         27
```

# Dictionary items() Method

### Description

The method items() returns a list of dict's (key, value) tuple pairs.

#### Syntax

Following is the syntax for items() method-

```
dict.items()
```

### **Parameters**

Z

### **Return Value**

This method returns a list of tuple pairs.

### Example

The following example shows the usage of items() method.

```
print ("Value : %s" %
                         dict = {'Name': 'Zara', 'Age': 7}
                                                   #!/usr/bin/python
 dict.items())
```

When we run the above program, it produces the following result-

```
Value : [('Age', 7), ('Name', 'Zara')]
```

## Dictionary keys() Method

### Description

The method keys() returns a list of all the available keys in the dictionary.

#### Syntax

Following is the syntax for keys() method-

```
dict.keys()
```

### **Parameters**

Z

### **Return Value**

This method returns a list of all the available keys in the dictionary.

### Example

The following example shows the usage of keys() method.

```
print ("Value :
                   dict = {'Name': 'Zara',
                                       #!/usr/bin/python3
 %s" %
dict.keys())
                   'Age': 7}
```

When we run the above program, it produces the following result-

```
Value : ['Age', 'Name']
```

# Dictionary setdefault() Method

### Description

already in dict. The method setdefault() is similar to get(), but will set dict[key]=default if the key is not

#### Syntax

Following is the syntax for setdefault() method-

```
dict.setdefault(key,
  default=None)
```

### **Parameters**

- key This is the key to be searched.
- default This is the Value to be returned in case key is not found.

### **Return Value**

available then it will return provided default value. This method returns the key value available in the dictionary and if given key is not

### Example

The following example shows the usage of setdefault() method

```
print ("Value : %s" %
                                                   print ("Value : %s" %
                                                                             dict = {'Name': 'Zara',
                                                                                                           #!/usr/bin/python3
(dict)
                           dict.setdefault('Sex', None))
                                                   dict.setdefault('Age', None))
                                                                                 'Age':
```

When we run the above program, it produces the following result-

```
Value :
{'Name': 'Zara',
                Value : None
'Sex': None,
 'Age':
7}
```

# Dictionary update() Method

### **Description**

The method **update()** adds dictionary dict2's key-values pairs in to dict. This function does not return anything.

#### Syntax

Following is the syntax for update() method-

```
dict.update(dict2)
```

### **Parameters**

dict2 - This is the dictionary to be added into dict.

### **Return Value**

This method does not return any value.

### Example

The following example shows the usage of update() method.

```
print ("updated dict : ", dict)
                                                  dict2 = {'Sex': 'female' }
                                                                                                      #!/usr/bin/python3
                            dict.update(dict2)
                                                                            {'Name': 'Zara',
                                                                             'Age':
```

When we run the above program, it produces the following result-

```
updated dict
 ••
 {'Sex': 'female',
 'Age':
7,
 'Name': 'Zara'}
```

# Dictionary values() Method

### Description

The method values() returns a list of all the values available in a given dictionary.

#### Syntax

Following is the syntax for values() method-

```
dict.values()
```

### **Parameters**

 $\stackrel{\mathsf{N}}{\sim}$ 

### **Return Value**

This method returns a list of all the values available in a given dictionary.

### Example

The following example shows the usage of values() method.

```
dict = {'Sex': 'female',
                    #!/usr/bin/python3
   'Age':
7,
   'Name': 'Zara'}
```

```
print ("Values : ", list(dict.values()))
```

When we run above program, it produces following result-

Values : ['female', 7, 'Zara']

# 14. Python 3 — Date & Time

dates and times. formats is a common chore for computers. Python's time and calendar modules help track A Python program can handle date and time in several ways. Converting between date

### What is Tick?

are expressed in seconds since 12:00am, January 1, 1970(epoch). Time intervals are floating-point numbers in units of seconds. Particular instants in time

There is a popular **time** module available in Python, which provides functions for working with times, and for converting between representations. The function **time.time()** returns the current system time in ticks since 12:00am, January 1, 1970(epoch).

### Example

```
print ("Number of ticks since 12:00am, January 1,
                            ticks = time.time()
                                                                    import time;
                                                                                                #!/usr/bin/python3
                                                                    # This
                                                                   is required to include time module
1970:",
ticks)
```

This would produce a result something as follows:

```
Number of ticks since 12:00am, January 1,
    1970:
    1455508609.34375
```

cutoff point is sometime in 2038 for UNIX and Windows. represented in this form. Dates in the far future also cannot be represented this way - the Date arithmetic is easy to do with ticks. However, dates before the epoch cannot be

### What is TimeTuple?

Many of the Python's time functions handle time as a tuple of 9 numbers, as shown below-

Index	Field	Values
0	4-digit year	2016
1	Month	1 to 12
2	Day	1 to 31

### For Example-

```
>>> print (time.localtime())
                              >>>import time
```

# This would produce a result as follows-

```
time.struct_time(tm_year=2016, tm_mon=2, tm_mday=15,
tm_sec=2, tm_wday=0, tm_yday=46, tm_isdst=0)
                            tm_hour=9,
                          tm_min=29,
```

The above tuple is equivalent to  ${\bf struct\_time}$  structure. This structure has the following attributes-

Index	Attributes	Values
0	tm_year	2016
1	tm_mon	1 to 12
2	tm_mday	1 to 31
ω	tm_hour	0 to 23
4	tm_min	0 to 59
5	tm_sec	0 to 61 (60 or 61 are leap-seconds)
6	tm_wday	0 to 6 (0 is Monday)

-1, 0, 1, -1 means library determines DST	tm_isdst	8
1 to 366 (Julian day)	tm_yday	7

### Getting current time

with all valid nine items tuple, pass the floating-point value to a function (e.g., localtime) that returns a time-tuple To translate a time instant from **seconds** since the epoch floating-point value into a time-

```
print ("Local current time :", localtime)
                                                                                                                                                                          #!/usr/bin/python3
                                              localtime = time.localtime(time.time())
                                                                                                                                     import time
```

form-This would produce the following result, which could be formatted in any other presentable

```
Local current time : time.struct_time(tm_year=2016, tm_mon=2,
tm_hour=9, tm_min=29, tm_sec=2, tm_wday=0, tm_yday=46, tm_isdst=0)
                                     tm_mon=2,
                                   tm_mday=15,
```

### Getting formatted time

You can format any time as per your requirement, but a simple method to get time in readable format is asctime() а

```
print ("Local current time :",
                                                                                                                                                   #!/usr/bin/python3
                                          localtime = time.asctime( time.localtime(time.time()) )
                                                                                                                  import time
    localtime)
```

This would produce the following result-

```
Local current time : Mon Feb 15 09:34:03 2016
```

# Getting calendar for a month

calendars. Here, we print a calendar for a given month ( Jan 2008 ). The calendar module gives a wide range of methods to play with yearly and monthly

```
#!/usr/bin/python3
import calendar
```

```
print (cal)
                       print ("Here is the calendar:")
                                                  cal
                                               calendar.month(2016, 2)
```

This would produce the following result-

```
22
             15
29
                                ŏ
                                              Here is the
                   œ
                                Tu We
             16
                                      February
                   9
                   10
             17

                                       2016
             19
                   12 13 14
      26
                                             calendar:
                          ъ
             20 21
      27
                          σ
      28
                                nS
```

### The time Module

There is a popular **time** module available in Python, which provides functions for working with times and for converting between representations. Here is the list of all available methods.

S	Function with Description
1	time.altzone
	The offset of the local DST timezone, in seconds west of UTC, if one is defined. This is negative if the local DST timezone is east of UTC (as in Western Europe, including the UK). Use this if the daylight is nonzero.
2	time.asctime([tupletime])
	Accepts a time-tuple and returns a readable 24-character string such as 'Tue Dec 11 18:07:14 2008'.
ω	time.clock( )
	Returns the current CPU time as a floating-point number of seconds. To measure computational costs of different approaches, the value of time.clock is more useful than that of time.time().
4	time.ctime([secs])
	Like asctime(localtime(secs)) and without arguments is like asctime()

I	
U	time.gmtime([secs])  Accepts an instant expressed in seconds since the epoch and returns a time-tuple t with the UTC time. Note: t.tm_isdst is always 0
6	time.localtime([secs])
	Accepts an instant expressed in seconds since the epoch and returns a time-tuple t with the local time (t.tm_isdst is 0 or 1, depending on whether DST applies to instant secs by local rules).
7	time.mktime(tupletime)
	Accepts an instant expressed as a time-tuple in local time and returns a floating-point value with the instant expressed in seconds since the epoch.
8	time.sleep(secs)
	Suspends the calling thread for secs seconds.
9	time.strftime(fmt[,tupletime])
	Accepts an instant expressed as a time-tuple in local time and returns a string representing the instant as specified by string fmt.
10	time.strptime(str,fmt='%a %b %d %H:%M:%S %Y')
	Parses str according to format string fmt and returns the instant in time-tuple format.
11	time.time( )
	Returns the current time instant, a floating-point number of seconds since the epoch.
12	time.tzset()
	Resets the time conversion rules used by the library routines. The environment variable TZ specifies how this is done.

Let us go through the functions briefly-

### Time altzone() Method

### **Description**

The method **altzone()** is the attribute of the time module. This returns the offset of the local DST timezone, in seconds west of UTC, if one is defined. This is negative if the local

daylight is nonzero. DST timezone is east of UTC (as in Western Europe, including the UK). Only use this if

#### Syntax

Following is the syntax for altzone() method-

time.altzone

### **Parameters**

Z

### **Return Value**

is defined. This method returns the offset of the local DST timezone, in seconds west of UTC, if one

### Example

The following example shows the usage of altzone() method

```
print ("time.altzone
                                     #!/usr/bin/python3
                    import time
  ••
. =
   time.altzone)
```

When we run the above program, it produces the following result-

```
time.altzone
-23400
```

### Time asctime() Method

### Description

The method asctime() converts a tuple or struct\_time representing a time as returned by gmtime() or localtime() to a 24-character string of the following form: 'Tue Feb 17 23:21:05 2009'.

#### Syntax

Following is the syntax for asctime() method-

```
time.asctime([t]))
```

### **Parameters**

or localtime() function. **t** - This is a tuple of 9 elements or struct\_time representing a time as returned by gmtime()

### **Return Value**

2009'. This method returns 24-character string of the following form: 'Tue Feb 17 23:21:05

### Example

The following example shows the usage of asctime() method.

```
import time
                                                              #!/usr/bin/python3
                     = time.localtime()
("asctime
..
",time.asctime(t))
```

When we run the above program, it produces the following result-

```
asctime :
Mon Feb
15 09:46:24 2016
```

### Time clock() Method

### Description

name, but in any case, this is the function to use for benchmarking Python or timing expressed in seconds on Unix. The precision depends on that of the C function of the same algorithms. The method clock() returns the current processor time as ۵ floating point number

QueryPerformanceCounter. On Windows, this function returns wall-clock seconds elapsed since the first call to this floating point number, based 9 N the Win32 function

#### Syntax

Following is the syntax for clock() method-

```
time.clock()
```

### **Parameters**

Z

### Return Value

to this function, as a floating point number. seconds on Unix and in Windows it returns wall-clock seconds elapsed since the first call This method returns the current processor time as a floating point number expressed in

### Example

The following example shows the usage of clock() method.

```
print (time.clock()
                                                                                                                                                                                                                def
 print (time.time() -
                         procedure()
                                                                       # measure wall time
                                                                                                                                                                 # measure process time
                                               t0 = time.time()
                                                                                                                    procedure()
                                                                                                                                          t0 = time.clock()
                                                                                                                                                                                                                                       import time
                                                                                                                                                                                                                                                            #!/usr/bin/python3
                                                                                                                                                                                                               procedure():
                                                                                                                                                                                      time.sleep(2.5)
t0,
                                                                                            t0,
 "seconds wall time")
                                                                                           "seconds process time")
```

When we run the above program, it produces the following result-

```
2.4993855364299096 seconds process
seconds
wall
time
                    time
```

Windows), clock usually measures the wall time since the program was started Note: Not all systems can measure the true process time. On such systems (including

### Time ctime() Method

### Description

time() is used. This function is equivalent to asctime(localtime(secs)). Locale information representing local time. If secs is not provided or None, the current time as returned by is not used by ctime(). The method ctime() converts a time expressed in seconds since the epoch to a string

#### Syntax

Following is the syntax for ctime() method-

```
time.ctime([
sec
```

### **Parameters**

**sec** - These are the number of seconds to be converted into string representation.

### Return Value

This method does not return any value

### Example

The following example shows the usage of ctime() method.

```
print
                                      #!/usr/bin/python3
                     import time
 ("ctime :
", time.ctime())
```

When we run the above program, it produces the following result-

```
ctime :
Mon Feb 15 09:55:34 2016
```

### Time gmtime() Method

### **Description**

The method gmtime() converts a time expressed in seconds since the epoch to a struct\_time in UTC in which the dst flag is always zero. If secs is not provided or None, the current time as returned by time() is used.

#### Syntax

Following is the syntax for gmtime() method-

```
time.gmtime([
sec
し
```

### **Parameters**

representation. These are the number of. seconds ţ be converted into structure struct\_time

### **Return Value**

This method does not return any value.

### Example

The following example shows the usage of gmtime() method

```
print ("gmtime :", time.gmtime(1455508609.34375))
                                                                                     #!/usr/bin/python3
                                            import time
```

When we run the above program, it produces the following result-

```
gmtime :
tm_min=56,
tm_sec=49, tm_wday=0,
               time.struct_time(tm_year=2016,
tm_yday=46,
               tm_mon=2,
tm_isdst=0)
             tm_mday=15,
              tm_hour=3,
```

### Time localtime() Method

### Description

dst flag is set to 1 when DST applies to the given time time. If secs is not provided or None, the current time as returned by time() is used. The The method localtime() is similar to gmtime() but it converts number of seconds to local

#### Syntax

Following is the syntax for localtime() method-

```
time.localtime([
sec
```

### **Parameters**

sec representation. These are the number of seconds to be converted into structure struct\_time

### Return Value

This method does not return any value.

### Example

The following example shows the usage of localtime() method.

```
print ("time.localtime()
                                          #!/usr/bin/python3
                     import time
 ••
%s"
time.localtime())
```

When we run the above program, it produces the following result-

```
time.localtime()
tm_hour=10,
tm_min=13,
tm_sec=50,
            time.struct
 tm_wday=0,
          _time(tm_year=2016,
tm_yday=46,
            tm_mon=2,
 ,t
_isdst=0)
          tm_mday=15,
```

### Time mktime() Method

### Description

The method mktime() is the inverse function of localtime(). Its argument is the struct\_time or full 9-tuple and it returns a floating point number, for compatibility with time().

will be raised. If the input value cannot be represented as a valid time, either OverflowError or ValueError

#### Syntax

Following is the syntax for mktime() method-

```
time.mktime(t)
```

### **Parameters**

t - This is the struct\_time or full 9-tuple

### **Return Value**

This method returns a floating point number, for compatibility with time().

### Example

The following example shows the usage of mktime() method.

```
print
                     print ("time.mktime(t) : %f" %
                                             d=time.mktime(t)
                                                                                             import time
                                                                                                                    #!/usr/bin/python3
                                                                     = (2016, 2, 15,
("asctime(localtime(secs)):
                                                                    10,
                                                                     13, 38, 1, 48, 0)
                        <u>a</u>
 %s"
 %
time.asctime(time.localtime(d)))
```

When we run the above program, it produces the following result-

```
asctime(localtime(secs)): Mon Feb 15
                                     time.mktime(t) : 1455511418.000000
     10:13:38
     2016
```

### Time sleep() Method

### Description

may be a floating point number to indicate a more precise sleep time. The method **sleep()** suspends execution for the given number of seconds. The argument

will terminate the sleep() following execution of that signal's catching routine. The actual suspension time may be less than that requested because any caught signal

#### Syntax

Following is the syntax for sleep() method-

```
time.sleep(t)
```

### **Parameters**

 $oldsymbol{t}$  - This is the number of seconds for which the execution is to be suspended.

### **Return Value**

This method does not return any value.

### Example

The following example shows the usage of sleep() method.

```
print ("End
                              print ("Start
                                               import time
                                                               #!/usr/bin/python3
               time.sleep(
: %s"
                                %s"
 %
                                %
time.ctime())
                               time.ctime())
```

When we run the above program, it produces the following result-

```
End
              Start
••
Mon Feb 15
             Mon Feb 15
12:08:47
             12:08:42 2016
2016
```

### Time strftime() Method

### Description

The method **strftime()** converts a tuple or struct\_time representing a time as returned by gmtime() or localtime() to a string as specified by the format argument.

If t is not provided, the current time as returned by localtime() is used. The format must be a string. An exception ValueError is raised if any field in t is outside of the allowed range.

#### Syntax

Following is the syntax for strftime() method-

```
time.strftime(format[,
<u>†</u>])
```

### **Parameters**

t - This is the time in number of seconds to be formatted.

format - This is the directive which would be used to format given time.

The following directives can be embedded in the format string-

### Directive

- %a abbreviated weekday name
- %A full weekday name
- %b abbreviated month name
- %B full month name
- %c preferred date and time representation
- %C century number (the year divided by 100, range 00 to 99)
- %d day of the month (01 to 31)
- %D same as %m/%d/%y
- %e day of the month (1 to 31)
- %g like %G, but without the century
- %G 4-digit year corresponding to the ISO week number (see %V).
- %h same as %b
- %H hour, using a 24-hour clock (00 to 23)
- %I hour, using a 12-hour clock (01 to 12)
- %j day of the year (001 to 366)
- %m month (01 to 12)
- %M minute
- %n newline character
- %p either am or pm according to the given time value
- %r time in a.m. and p.m. notation
- %R time in 24 hour notation
- %S second
- %t tab character
- %T current time, equal to %H:%M:%S
- %u weekday as a number (1 to 7), Monday=1. Warning: In Sun Solaris Sunday=1
- day of the first week %U - week number of the current year, starting with the first Sunday as the first

- the first week that has at least 4 days in the current year, and with Monday as the % V - The ISO 8601 week number of the current year (01 to 53), where week 1 is first day of the week
- day of the first week %W - week number of the current year, starting with the first Monday as the first
- %w day of the week as a decimal, Sunday=0
- %x preferred date representation without the time
- %X preferred time representation without the date
- %y year without a century (range 00 to 99)
- %Y year including the century
- %Z or %z time zone or name or abbreviation
- %% a literal % character

### **Return Value**

This method does not return any value.

### Example

The following example shows the usage of strftime() method

```
print
                                           import time
                                                         #!/usr/bin/python3
               time.mktime(t)
                             (2015, 12, 31,
 (time.strftime("%b
                            10,
                            39,
 %д
                             45,
 %
%H:%M:%S",
                            1,
                             48, 0)
time.localtime(t)))
```

When we run the above program, it produces the following result-

```
Dec
2015
10:39:45
```

### Time strptime() Method

### Description

return value is a struct\_ The method strptime() parses a string representing a time according to \_time as returned by gmtime() or localtime(). а format. The

"%a %b %d %H:%M:%S %Y" which matches the formatting returned by ctime(). The format parameter uses the same directives as those used by strftime(); it defaults to

ValueError is raised. If string cannot be parsed according to format, or if it has excess data after parsing,

#### **Syntax**

Following is the syntax for strptime() method-

time.strptime(string[, format])

### **Parameters**

- format. string -This is the time in string format which would be parsed based on the given
- format This is the directive which would be used to parse the given string

### Directive

The following directives can be embedded in the format string-

- %a abbreviated weekday name
- %A full weekday name
- %b abbreviated month name
- %B full month name
- %c preferred date and time representation
- %C century number (the year divided by 100, range 00 to 99)
- %d day of the month (01 to 31)
- %D same as %m/%d/%y
- %e day of the month (1 to 31)
- %g like %G, but without the century
- %G 4-digit year corresponding to the ISO week number (see %V).
- %h same as %b
- %H hour, using a 24-hour clock (00 to 23)
- %I hour, using a 12-hour clock (01 to 12)
- %j day of the year (001 to 366)
- %m month (01 to 12)
- %M minute
- %n newline character
- %p either am or pm according to the given time value
- %r time in a.m. and p.m. notation
- %R time in 24 hour notation
- %S second
- %t tab character
- %T current time, equal to %H:%M:%S
- %u weekday as a number (1 to 7), Monday=1. Warning: In Sun Solaris Sunday=1
- day of the first week %U - week number of the current year, starting with the first Sunday as the first

- %V The ISO 8601 week number of the current year (01 to 53), where week 1 is the first week that has at least 4 days in the current year, and with Monday as the first day of the week
- day of the first week %W - week number of the current year, starting with the first Monday as the first
- %w day of the week as a decimal, Sunday=0
- %x preferred date representation without the time
- %X preferred time representation without the date
- %y year without a century (range 00 to 99)
- %Y year including the century
- %Z or %z time zone or name or abbreviation
- %% a literal % character

### Return Value

This return value is struct\_time as returned by gmtime() or localtime().

### Example

The following example shows the usage of strptime() method

```
print ("tuple
                                                   #!/usr/bin/python3
                                    import time
                   struct
                  _time
: ", struct_time)
                  time.strptime("30
                   12
                  2015",
                   ("Y% m% b%")
```

When we run the above program, it produces the following result-

```
tm_min=0,
tm_sec=0, tm_wday=2,
               time.struct_time(tm_year=2015,
tm_yday=364,
tm_isdst=-1)
                 tm_mon=12,
               tm_mday=30,
                 tm_hour=0,
```

### Time time() Method

### Description

the epoch, in UTC. The method time() returns the time as a floating point number expressed in seconds since

has been set back between the two calls non-decreasing values, it can return a lower value than a previous call if the system clock provide time with a better precision than f 1 second. While this function normally returns **Note:** Even though the time is always returned as a floating point number, not all systems

#### Syntax

Following is the syntax for time() method-

```
time.time()
```

### **Parameters**

Z

### Return Value

epoch, in UTC. This method returns the time as a floating point number expressed in seconds since the

### Example

The following example shows the usage of time() method.

```
print
print (time.asctime( time.localtime(time.time()) ))
                                   print (time.localtime( time.time() ))
                                                                                                            import time
                                                                                                                                             #!/usr/bin/python3
                                                                      ("time.time(): %f " %
                                                                       time.time())
```

When we run the above program, it produces the following result-

```
Mon Feb 15 12:33:26 2016
                                  tm_sec=26, tm_wday=0, tm_yday=46, tm_isdst=0)
                                                           time.struct_time(tm_year=2016,
                                                                                                time.time(): 1455519806.011433
                                                           tm_mon=2,
                                                      tm_mday=15,
                                                            tm_hour=12,
                                                            tm_min=33,
```

### Time tzset() Method

### Description

The method **tzset()** resets the time conversion rules used by the library routines. The environment variable TZ specifies how this is done.

The standard format of the TZ environment variable is (whitespace added for clarity)-

```
offset [dst
[offset [,start[/time], end[/time]]]]
```

- **std and dst:** Three or more alphanumerics giving the timezone abbreviations. These will be propagated into time.tzname.
- Meridian; otherwise, it is west. If no offset follows dst, summer time is assumed to be one hour ahead of standard time. local time to arrive at UTC. If preceded by a '-', the timezone is east of the Prime **offset:** The offset has the form: .hh[:mm[:ss]]. This indicates the value added the

- start[/time], end[/time]: Indicates when to change to and back from DST. The format of the start and end dates are one of the following:
- **Jn**: The Julian day n (1 <= n <= 365). Leap days are not counted, so in all years February 28 is day 59 and March 1 is day 60.

0

- 0 possible to refer to February 29.  $\mathbf{n}$ : The zero-based Julian day (0 <= n <= 365). Leap days are counted, and it is
- 0 the d'th day occurs. Day zero is Sunday. may occur in either the fourth or the fifth week). Week 1 is the first week in which **Mm.n.d**: The d'th day  $(0 \le d \le 6)$  or week n of month m of the year (1<= 5, 1 <= m <= 12, where week 5 means 'the last d day in month m' which
- 0 **time**: This has the same format as offset except that no leading sign ('-' or '+') is allowed. The default, if time is not given, is 02:00:00.

#### Syntax

Following is the syntax for tzset() method-

```
time.tzset()
```

### **Parameters**

Ν

### **Return Value**

This method does not return any value.

### Example

The following example shows the usage of tzset() method

```
print
                                                     os.environ['TZ']
                             time.tzset()
                                                                                                               print time.strftime('%X %x %Z')
                                                                                                                                           time.tzset()
                                                                                                                                                                     os.environ['TZ'] =
                                                                                                                                                                                                                              import os
                                                                                                                                                                                                                                                         import time
                                                                                                                                                                                                                                                                                      #!/usr/bin/python3
 time.strftime('%X %x %Z')
                                                         П
                                                     'AEST-10AEDT-11,M10.5.0,M3.5.
                                                                                                                                                                      'EST+05EDT,M4.1.0,M10.5.0'
```

When we run the above program, it produces the following result-

13:00:40 02/17/09 EST

05:00:40 02/18/09 AEDT

There are two important attributes available with time module. They are-

### The calendar Module

calendar for a given month or year. The calendar module supplies calendar-related functions, including functions to print a text

one. To change this, call the calendar.setfirstweekday() function. By default, calendar takes Monday as the first day of the week and Sunday as the last

Here is a list of functions available with the calendar module-

Returns a multiline string with a calendar for year year formatted into three columns separated by c spaces. w is the width in characters of each date; each line has length $21*w+18+2*c$ . I is the number of lines for each week.

11	10	9	8	7	6	U	4	ω	2
calendar.timegm(tupletime)  The inverse of time.gmtime: accepts a time instant in time-tuple form and returns the same instant as a floating-point number of seconds since the epoch.	calendar.setfirstweekday(weekday)  Sets the first day of each week to weekday code weekday. Weekday codes are 0 (Monday) to 6 (Sunday).	<pre>calendar.prmonth(year,month,w=2,l=1) Like print calendar.month(year,month,w,l).</pre>	<pre>calendar.prcal(year,w=2,l=1,c=6)</pre> Like print calendar.calendar(year,w,l,c).	calendar.monthrange(year,month)  Returns two integers. The first one is the code of the weekday for the first day of the month month in year; the second one is the number of days in the month.  Weekday codes are 0 (Monday) to 6 (Sunday); month numbers are 1 to 12.	calendar.monthcalendar(year,month)  Returns a list of lists of ints. Each sublist denotes a week. Days outside month month of year year are set to 0; days within the month are set to their day-ofmonth, 1 and up.	calendar.month(year,month,w=2,I=1)  Returns a multiline string with a calendar for month month of year year, one line per week plus two header lines. w is the width in characters of each date; each line has length 7*w+6. I is the number of lines for each week.	calendar.leapdays(y1,y2)  Returns the total number of leap days in the years within range(y1,y2).	calendar.isleap(year) Returns True if year is a leap year; otherwise, False.	calendar.firstweekday()  Returns the current setting for the weekday that starts each week. By default, when calendar is first imported, this is 0, meaning Monday.

	12
Returns the weekday code for the given date. Weekday codes are 0 (Monday) to 6 (Sunday); month numbers are 1 (January) to 12 (December).	calendar.weekday(year,month,day)

# Other Modules & Functions

If you are interested, then here you would find a list of other important modules and functions to play with date & time in Python-

- The datetime Module
- The pytz Module
- The dateutil Module

# 15. Python 3 — Functions

A function is a block of organized, reusable code that is used to perform a single, related action. Functions provide better modularity for your application and a high degree of code

As you already know, Python gives you many built-in functions like print(), etc. but you can also create your own functions. These functions are called *user-defined functions*.

### **Defining a Function**

define a function in Python. You can define functions to provide the required functionality. Here are simple rules

- parentheses ( ( ) ). Function blocks begin with the keyword def followed by the function name and
- You can also define parameters inside these parentheses Any input parameters or arguments should be placed within these parentheses.
- string of the function or docstring. The first statement of a function can be an optional statement - the documentation
- The code block within every function starts with a colon (:) and is indented
- expression to the caller. A return statement with no arguments is the same as The statement return [expression] exits a function, optionally passing back an

#### Syntax

```
def functionname( parameters
                                 function_suite
return [expression]
                                                                  "function_docstring"
                                                                                                        \stackrel{\smile}{:}
```

same order that they were defined. By default, parameters have a positional behavior and you need to inform them in the

### Example

The following function takes a string as input parameter and prints it on the standard

```
def printme( str ):
print
                  "This prints
                   മ
                  passed
                  string
                  into this function"
```

return

### Calling a Function

Defining a function gives it a name, specifies the parameters that are to be included in the function and structures the blocks of code.

printme() functionanother function or directly from the Python prompt. Following is an example to call the Once the basic structure of a function is finalized, you can execute it by calling it from

```
printme("This is first call to the user defined function!")
                                                                                     # Now you can call printme function
                                                                                                                                                                                                                                                                                                                                                                                                                                       #!/usr/bin/python3
printme("Again second call to the same function")
                                                                                                                                                                                                                                                                                                          def printme( str ):
                                                                                                                                                                                                                                                                                                                                                   Function definition
                                                                                                                                                                             return
                                                                                                                                                                                                                    print (str)
                                                                                                                                                                                                                                                          "This prints a passed string into this function"
                                                                                                                                                                                                                                                                                                                                                      15
                                                                                                                                                                                                                                                                                                                                                      here
```

When the above code is executed, it produces the following result-

```
This
Again second call to the same function
                                      first call to the user defined
                                    function!
```

# Pass by Reference vs Value

the calling function. For example-All parameters (arguments) in the Python language are passed by reference. It means if you change what a parameter refers to within a function, the change also reflects back in

```
def changeme( mylist ):
                                                                                                                                                                                                                   # Function definition is here
                                                                                                                                                                                                                                                                                                     #!/usr/bin/python3
                                         mylist[2]=50
                                                                                 print ("Values inside the function before change:
print ("Values
                                                                                                                             "This changes a passed list into this function"
inside the function after change: ", mylist)
                                                                            ", mylist)
```

```
print ("Values outside the function: ", mylist)
                                          changeme( mylist )
                                                                                     mylist = [10, 20, 30]
                                                                                                                                   # Now you can call changeme function
```

Here, we are maintaining reference of the passed object and appending values in the object. Therefore, this would produce the following resultsame

```
Values outside the function:
                                                    Values
                          Values
                                                inside the function before change:
                          inside the function after change:
[10, 20, 50]
                          [10, 20, 50]
                                                [10,
                                                20, 30]
```

reference is being overwritten inside the called function. one more example where argument is being passed by reference and the

```
print ("Values outside the
                                                                                       mylist =
                                                                                                                                   # Now you can call changeme function
                                                                                                                                                                                                                                                                                                                                                                                              def changeme( mylist ):
                                                                                                                                                                                                                                                                                                                                                                                                                                            # Function definition is here
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            #!/usr/bin/python3
                                          changeme( mylist )
                                                                                                                                                                                                                                                                                                          mylist = [1,2,3,4] # This would assi new reference in mylist
                                                                                                                                                                                                                                                             print ("Values inside the function: ", mylist)
                                                                                                                                                                                                                                                                                                                                                   "This changes a passed list into this function"
                                                                                       [10,20,30]
function: ", mylist)
```

function does not affect mylist. The function accomplishes nothing and finally this would produce the following result-The parameter mylist is local to the function changeme. Changing mylist within the

```
Values outside the function:
                 Values inside the function:
                [1, 2,
[10,
20,
                'n
 30]
                4
```

### **Function Arguments**

You can call a function by using the following types of formal arguments-

- Required arguments
- Keyword arguments
- Default arguments
- Variable-length arguments

### Required Arguments

definition. Here, the number of arguments in the function call should match exactly with the function Required arguments are the arguments passed to a function in correct positional order.

To call the function printme(), you definitely need to pass one argument, otherwise it gives syntax error as follows-

```
printme()
                                    # Now you can call printme function
                                                                                                                                                                                                  def printme( str ):
                                                                                                                                                                                                                                          # Function definition is here
                                                                                                                                                                                                                                                                             #!/usr/bin/python3
                                                                                                                 print (str)
                                                                                                                                                           "This prints a passed string into this function"
```

When the above code is executed, it produces the following result-

```
TypeError: printme() missing
                                                                                                 Traceback (most recent call last):
                                                                   File "test.py",
                                    printme()
                                                                   line 11, in <module>
     \vdash
  required positional argument:
      'str'
```

### **Keyword Arguments**

in a function call, the caller identifies the arguments by the parameter name Keyword arguments are related to the function calls. When you use keyword arguments

interpreter is able to use the keywords provided to match the values with parameters. You can also make keyword calls to the printme() function in the following ways-This allows you to skip arguments or place them out of order because the Python

```
#!/usr/bin/python3
 # Function definition is
here
```

```
printme( str = "My string")
                                        # Now you can call printme function
                                                                                                                                                                                                           def printme( str ):
                                                                                                                        print (str)
                                                                                                                                                                  "This prints a passed string into this function"
```

When the above code is executed, it produces the following result-

```
My string
```

matter. The following example gives a clearer picture. Note that the order of parameters does not

```
printinfo( age=50, name="miki" )
                                           # Now you can call printinfo function
                                                                                                                                                                                                                                                                                                                                                                                                                  #!/usr/bin/python3
                                                                                                                                                                                                                                                                                         def printinfo( name, age ):
                                                                                                                                                                                                                                                                                                                                  Function definition is here
                                                                                                                                                                   print ("Age ", age)
                                                                                                                                                                                                       print ("Name: ", name)
                                                                                                                                                                                                                                                  "This prints a passed info into this function"
```

When the above code is executed, it produces the following result-

```
Age
        Name:
50
       miki
```

### Default Arguments

A default argument is an argument that assumes a default value if a value is not provided in the function call for that argument. The following example gives an idea on default arguments, it prints default age if it is not passed.

```
def printinfo( name, age = 35 ):
                                                                                                                       # Function definition is here
                                                                                                                                                                                                     #!/usr/bin/python3
print ("Name: ", name)
                                          "This prints a passed info into this function"
```

```
printinfo( age=50, name="miki"
printinfo( name="miki"
                                                                          # Now you can call printinfo function
                                                                                                                                                   print ("Age ", age)
```

When the above code is executed, it produces the following result-

```
Age
                   Age
                              Name:
          Name: miki
                    50
                              miki
```

## Variable-length Arguments

the function definition, unlike required and default arguments. You may need to process a function for more arguments than you specified while defining the function. These arguments are called *variable-length* arguments and are not named in

Syntax for a function with non-keyword variable arguments is given below-

```
def functionname([formal_args,] *var_args_tuple ):
return [expression]
                                   function_suite
                                                                         "function_docstring"
```

during the function call. Following is a simple examplevariable arguments. This tuple remains empty if no additional arguments are specified An asterisk (\*) is placed before the variable name that holds the values of all nonkeyword

```
printinfo( 70,
                             printinfo( 10 )
                                                          # Now you can call printinfo function
                                                                                                                                                                                                                                                                                                          # Function definition is here
                                                                                                                                                                                                                                                                                                                                                                       #!/usr/bin/python3
                                                                                                                                                                                                                                                                            def printinfo( arg1, *vartuple
                                                                                           return
                                                                                                                                                                                   print (arg1)
                                                                                                                                                                                                                print ("Output is: ")
                                                                                                                                                                                                                                           "This prints a variable passed arguments"
                                                                                                                                                     for var in vartuple:
                                                                                                                       print (var)
 ,
 50)
```

When the above code is executed, it produces the following result-

```
60
          70
                     Output is:
                                            Output is:
```

## The Anonymous Functions

manner by using the def keyword. You can use the lambda keyword anonymous functions. These functions are called anonymous because they are not declared ф in the standard create small

- Lambda forms can take any number of arguments but return just one value in the form of an expression. They cannot contain commands or multiple expressions.
- expression. An anonymous function cannot be a direct call to print because lambda requires an
- other than those in their parameter list and those in the global namespace. Lambda functions have their own local namespace and cannot access variables
- by passing function, during invocation for performance reasons equivalent to inline statements in C or C++, whose purpose is to stack allocation Although it appears that lambdas are a one-line version of a function, they are not

#### Syntax

The syntax of lambda function contains only a single statement, which is as follows

```
lambda
[arg1
[,arg2,....argn]]:expression
```

Following is an example to show how lambda form of function works-

```
# Function definition is here
                                                                                                                                                                                                                #!/usr/bin/python3
 print ("Value of total :
                                print ("Value of total
                                                                                                                        sum = lambda arg1, arg2: arg1 + arg2
                                                            # Now you can call sum as a function
                                ••
                        ζ=
sum( 20, 20 ))
                               sum( 10, 20 ))
```

When the above code is executed, it produces the following result-

```
Value
Value of total :
           of total
           ••
40
           30
```

## The return Statement

The statement return [expression] exits a function, optionally passing back an expression to the caller. A return statement with no arguments is the same as return None.

All the examples given above are not returning any value. You can return a value from a function as follows-

```
total
    print ("Outside the function :
                                                       # Now you can call sum function
                                                                                                                                                                                                                                                                                       #!/usr/bin/python3
                                                                                                                                                                                                           def sum( arg1, arg2 ):
                                                                                                                                                                                                                                      Function definition is here
                                                                                                                                                                                 # Add both the parameters and return them."
                                                                                                                                print ("Inside the function :
                                                                                                                                                         total = arg1 + arg2
                                                                                                          return
                            = sum( 10,
                                                                                                          total
                             20 )
ς=
                                                                                                                             . =
    total )
                                                                                                                                  total)
```

When the above code is executed, it produces the following result-

```
Outside the function :
                      Inside the function :
                      30
30
```

### Scope of Variables

depends on where you have declared a variable All variables in a program may not be accessible at all locations in that program. This

The scope of a variable determines the portion of the program where you can access a particular identifier. There are two basic scopes of variables in Python-

- Global variables
- Local variables

## Global vs. Local variables

outside have a global scope. Variables that are defined inside a function body have a local scope, and those defined

functions. When you call a function, the variables declared inside it are brought into scope. declared, whereas global variables can be accessed throughout the program body by all Following is a simple example-This means that local variables can be accessed only inside the function in which they are

```
print ("Outside the function global total :
                                                                                                                                                                                                                                                                                                                                                                     def sum( arg1, arg2 ):
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                           #!/usr/bin/python3
                                              sum( 10, 20 )
                                                                                              # Now you can call sum function
                                                                                                                                                                                                                                                                                                                                                                                                                     # Function definition is here
                                                                                                                                                                                                                                                                                                                                                                                                                                                                total = 0 # This is global variable.
                                                                                                                                                                                                                                print ("Inside the function local total : ", total)
                                                                                                                                                                                                                                                                                total = arg1 + arg2; # Here total is local variable.
                                                                                                                                                                                                                                                                                                                        # Add both the parameters and return them."
                                                                                                                                                                                         return total
     total )
```

When the above code is executed, it produces the following result-

```
Outside the function global total :
                                  Inside the function local total :
                                    30
    0
```

# 16. Python 3 - Modules

A module allows you to logically organize your Python code. Grouping related code into a module makes the code easier to understand and use. A module is a Python object with arbitrarily named attributes that you can bind and reference.

Simply, a module is a file consisting of Python code. A module can define functions, classes and variables. A module can also include runnable code.

#### Example

Here is an example of a simple module, support.py. The Python code for a module named aname normally resides in a file namedaname.py.

```
def print_func( par ):
                  print "Hello :
return
               ", par
```

## The import Statement

You can use any Python source file as a module by executing an import statement in some other Python source file. The import has the following syntax-

```
import module1[, module2[,... moduleN]
```

is present in the search path. A search path is a list of directories that the interpreter need to put the following command at the top of the scriptsearches before importing a module. When the interpreter encounters an import statement, it imports the module if the module For example, to import the module hello.py, you

```
# Now you can call defined function that module
                                                                     import support
                                                                                                                                             #!/usr/bin/python3
support.print_func("Zara")
                                                                                                           # Import module support
                                   as follows
```

When the above code is executed, it produces the following result-

```
Zara
```

A module is loaded only once, regardless of the number of times it is imported. prevents the module execution from happening repeatedly, if multiple imports occur. This

## The from...import Statement

Python's **from** statement lets you import specific attributes from a module into the namespace. The **from...import** has the following syntaxcurrent

```
from modname import name1[, name2[,
... nameN]]
```

statement-For example, ç import the function fibonacci from the module fib, esn the following

```
def
                                                                                                                                                                                                           #!/usr/bin/python3
                                                                                                                                                                             Fibonacci numbers module
1, 2, 3,
                                                                                                                             result
                fib(100)
                                from fib import fib
                                                                                                                                              fib(n): # return Fibonacci
                                                                                               while b < n:
                                                 return result
                                                                                                               σ

                                                                            while b < n:
                         _name
                                                                                         ь
П
                                                  a
                                                              result.append(b)
                                                    ь
П
                                                                                         Ô
                                                                                                      II
                                                                                                                  # return Fibonacci
                                                                                                     Н
                                                  ٩
                         _main
                                                                                                                  series
                                                                                                                  ч
                                                                                                                   tο
                                                                                                                   ⊐
```

When you run the above code, the following output will be displayed

```
[1,
2,
'n
2
13,
21,
34,
55,
89]
```

### **Locating Modules**

sequences-When you import a module, the Python interpreter searches for the module in the following

- The current directory.
- **PYTHONPATH** If the module is not found, Python then searches each directory in the shell variable
- normally /usr/local/lib/python3/. If all else fails, Python checks the default path. On UNIX, this default path is

The module search path is stored in the system module sys as the **sys.path** variable. The sys.path variable contains the current directory, PYTHONPATH, and the installationdependent default.

## The PYTHONPATH Variable

of PYTHONPATH is the same as that of the shell variable PATH. The PYTHONPATH is an environment variable, consisting of a list of directories. The syntax

Here is a typical PYTHONPATH from a Windows system-

```
PYTHONPATH=c:\python34\lib;
```

And here is a typical PYTHONPATH from a UNIX system-

```
| set PYTHONPATH=/usr/local/lib/python
```

## Namespaces and Scoping

variable names (keys) and their corresponding objects (values). Variables are names (identifiers) that map to objects. A namespace S ۵ dictionary 으

- shadows the global variable namespace. If a local and a global variable have the same name, A Python statement can access variables in a local namespace and in the global the local variable
- rule as ordinary functions. Each function has its own local namespace. Class methods follow the same scoping
- assumes that any variable assigned a value in a function is local. Python makes educated guesses on whether variables are local 윽 global. It
- first use the global statement. Therefore, in order to assign a value to a global variable within a function, you must
- Python stops searching the local namespace for the variable The statement global VarName tells Python that VarName <u>s</u> മ global variable.

For function Money, we variable. example, ¥e assign Money a value, therefore Python assumes Money as define ۵ variable Money in the global namespace. Within ۵ local the

UnboundLocalError is the result. Uncommenting the global statement fixes the problem. However, we accessed the value of the local variable Money before setting it, an

```
print (Money)
                                                                                                                                                                                                                                                                         #!/usr/bin/python3
                         AddMoney()
                                                  print (Money)
                                                                                                                                                                                         def AddMoney():
                                                                                                                                                                                                                  Money = 2000
                                                                                                         Money = Money +
                                                                                                                                  # global Money
                                                                                                                                                              # Uncomment the following line to fix the code:
                                                                                                           Н
```

### The dir() Function

a module, The dir() built-in function returns a sorted list of strings containing the names defined by

a module. Following is a simple example-The list contains the names of all the modules, variables and functions that are defined in

```
print (content)
                                                                                                     # Import built-in module math
                                                                                                                                     #!/usr/bin/python3
                                 content = dir(math)
```

When the above code is executed, it produces the following result-

```
'log10',
                                                            'atan2',
                                                                               _'_doc_
'sqrt', 'tan', 'tanh']
                   'modf',
                                      'floor',
                                                                               \_-
_-
                                                           'ceil',
                                                                               _file__',
                  'pi',
                                                         'cos',
                                       'fmod',
                  'pow', 'radians', 'sin', 'sinh',
                                                          'cosh', 'degrees',
                                      'frexp', 'hypot', 'ldexp', 'log',
                                                                              __name___', 'acos',
                                                          'e', 'exp'
                                                                               'asin', 'atan',
```

Here, the special string variable \_\_\_name\_\_ filename from which the module was loaded. S. the module's name, and file <u></u>. the

# The globals() and locals() Functions

local namespaces depending on the location from where they are called. The globals() and locals() functions can be used to return the names in the global and

- If locals() is called from within a function, it will return all the names that can be accessed locally from that function.
- If globals() is called from within a function, it will return all the names that can accessed globally from that function.

using the **keys()** function. The return type of both these functions is dictionary. Therefore, names can be extracted

## The reload() Function

executed only once When a module is imported into a script, the code in the top-level portion of a module is

Therefore, if you want to reexecute the top-level code in a module, you can use the reload() function. The reload() function imports a previously imported module again. The syntax of the reload() function is this-

```
reload(module_name)
```

containing the module name. For example, to reload hello module, do the following-Here, module\_name is the name of the module you want to reload and not the string

```
reload(hello)
```

## Packages in Python

environment that consists of modules and subpackages and sub-subpackages, and so on. A package is a hierarchical file directory structure that defines a single Python application

source code-Consider a file Pots.py available in Phone directory. This file has the following line of

```
def Pots():
                                                      #!/usr/bin/python3
print ("I'm Pots Phone")
```

They are Similarly, we have other two files having different functions with the same name as above.

- Phone/Isdn.py file having function Isdn()
- Phone/G3.py file having function G3()

Now, create one more file \_init\_\_\_.py in the *Phone* directory-

Phone/\_\_init\_\_.py

explicit import statements in To make all of your functions available when you have imported Phone, you need to put ˈnitˌ \_.py as follows-

```
from G3 import G3
                                                          from Pots import Pots
                             Isdn import Isdn
```

import the Phone package After you add these lines to \_init\_ \_.py, you have all of these classes available when you

```
Phone.Isdn()
                                                    Phone.Pots()
                                                                                                                                 #!/usr/bin/python3
Phone.G3()
                                                                             import Phone
                                                                                                        Now import your Phone Package
```

When the above code is executed, it produces the following result-

I'm Pots Phone

I'm 3G Phone

I'm ISDN Phone

In the above example, we have taken example of a single function in each file, but you can keep multiple functions in your files. You can also define different Python classes in those files and then you can create your packages out of those classes.

# 17. Python 3 — Files I/O

please refer to the standard Python documentation. This chapter covers all the basic I/O functions available in Python 3. For more functions,

## Printing to the Screen

pass into a string and writes the result to standard output as follows or more expressions separated by commas. This function converts the expressions you The simplest way to produce output is using the print statement where you can pass zero

```
#!/usr/bin/python3
 ("Python is
  really
a great language,",
   "isn't
  it?")
```

This produces the following result on your standard screen-

```
Python is really a great language, isn't it?
```

## Reading Keyboard Input

comes from the keyboard. These functions are input() and raw\_input() Python 2 has two built-in functions to read data from standard input, which by default

In Python 3, raw\_input() function is deprecated. Moreover, input() functions read data from keyboard as string, irrespective of whether it is enclosed with quotes (" or "" ) or

## The input Function

input is a valid Python expression and returns the evaluated result to you. The input([prompt]) function is equivalent to raw\_input, except that it assumes that the

```
"'10'"
                                                                                                                                                                                                                                                                                                                                                                      #!/usr/bin/python3
                                                                              something: '10' #entered data treated as string with or without
                                                                                                                      >>> x=input("something:")
                                                                                                                                                                                                                                                something:10
                                                                                                                                                                                                                                                                                    >>> x=input("something:")
```

## **Opening and Closing Files**

Until now, you have been reading and writing to the standard input and output. Now, we will see how to use actual data files.

can do most of the file manipulation using a file object. Python provides basic functions and methods necessary to manipulate files by default. You

## The open Function

support methods associated with it. open() function. This function creates a file object, Before can read 윽 write ۵ file, you have which would be utilized to call other to open it using Python's built-in

#### **Syntax**

```
file object
  П
open(file_name
C
access_mode][,
 buffering])
```

Here are parameter details-

- the file that you want to access. file\_name: The file\_name argument is a string value that contains the name of
- opened, i.e., read, write, append, etc. A complete list of possible values is given below in the table. This is an optional parameter and the default file access mode access\_mode: The access\_mode determines the mode in which the file has to be is read (r).
- with the indicated buffer size. If negative, the buffer size is the system default buffering value is 1, line buffering is performed while accessing a file. If you specify the buffering value as an integer greater than 1, then buffering action is performed buffering: If the buffering value is set to 0, no buffering takes (default behavior). place. If the

Here is a list of the different modes of opening a file-

Modes	Description
٦	Opens a file for reading only. The file pointer is placed at the beginning of the file. This is the default mode.
rb	Opens a file for reading only in binary format. The file pointer is placed at the beginning of the file. This is the default mode.
7	Opens a file for both reading and writing. The file pointer placed at the beginning of the file.

ab+	a +	ab	а	wb+	<b>V</b> +	wb	¥	rb+
Opens a file for both appending and reading in binary format. The file pointer is at the end of the file if the file exists. The file opens in the append mode. If the file does not exist, it creates a new file for reading and writing.	Opens a file for both appending and reading. The file pointer is at the end of the file if the file exists. The file opens in the append mode. If the file does not exist, it creates a new file for reading and writing.	Opens a file for appending in binary format. The file pointer is at the end of the file if the file exists. That is, the file is in the append mode. If the file does not exist, it creates a new file for writing.	Opens a file for appending. The file pointer is at the end of the file if the file exists. That is, the file is in the append mode. If the file does not exist, it creates a new file for writing.	Opens a file for both writing and reading in binary format. Overwrites the existing file if the file exists. If the file does not exist, creates a new file for reading and writing.	Opens a file for both writing and reading. Overwrites the existing file if the file exists. If the file does not exist, creates a new file for reading and writing.	Opens a file for writing only in binary format. Overwrites the file if the file exists. If the file does not exist, creates a new file for writing.	Opens a file for writing only. Overwrites the file if the file exists. If the file does not exist, creates a new file for writing.	Opens a file for both reading and writing in binary format. The file pointer placed at the beginning of the file.

## The file Object Attributes

Once a file is opened and you have one  $\it file$  object, you can get various information related to that file.

Here is a list of all the attributes related to a file object-

Attribute	Description
file.closed	Returns true if file is closed, false otherwise.

file.name	file.mode
Returns name of the file.	Returns access mode with which file was opened.

**Note:** softspace attribute is not supported in Python 3.x

#### Example

```
print ("Opening mode : ", fo.mode)
                                                              print ("Closed or not : ", fo.closed)
                                                                                               print ("Name of the file: ", fo.name)
                                                                                                                                                                                                                                    #!/usr/bin/python3
                                                                                                                                                                    # Open a file
fo.close()
                                                                                                                                   fo = open("foo.txt",
                                                                                                                                    "wb")
```

This produces the following result-

```
Opening mode : wb
                      Closed or not :
                                             Name of the file:
                       False
                                             foo.txt
```

## The close() Method

The close() method of a file object flushes any unwritten information and closes the file object, after which no more writing can be done.

Python automatically closes a file when the reference object of a file is reassigned to another file. It is a good practice to use the close() method to close a file.

#### Syntax

```
fileObject.close();
```

#### Example

```
print ("Name of the file: ", fo.name)
                                                             # Open a file
                            fo = open("foo.txt", "wb")
                                                                                                                              #!/usr/bin/python3
```

```
fo.close()
                 Close opened
```

This produces the following result-

```
Name
of.
the
file:
foo.txt
```

## Reading and Writing Files

The file object provides a set of access methods to make our lives easier. We would see how to use read() and write() methods to read and write files.

## The write() Method

The write() method writes any string to an open file. It is important to note that Python strings can have binary data and not just text.

The write() method does not add a newline character ('\n') to the end of the string-

#### Syntax

```
fileObject.write(string);
```

Here, passed parameter is the content to be written into the opened file

#### Example

```
fo = open("foo.txt", "w")
                                                                                                                                                                                                                        #!/usr/bin/python3
fo.close()
                                                                                          fo.write( "Python is
                                                                                                                                                          # Open a file
                               Close opend file
                                                                                          a great language.\nYeah its great!!\n")
```

finally it would close that file. If you would open this file, it would have the following The above method would create foo.txt file and would write given content in that file and content-

```
Yeah its great!!
                       Python is a great
                       language.
```

## The read() Method

The read() method reads a string from an open file. It is important to note that Python strings can have binary data apart from the text data.

#### Syntax

```
fileObject.read([count]);
```

method starts reading from the beginning of the file and if count is missing, then it tries to read as much as possible, maybe until the end of file. Here, passed parameter is the number of bytes to be read from the opened file. This

#### Example

Let us take a file foo.txt, which we created above.

```
str =
                                       print ("Read String
                                                                               fo = open("foo.txt", "r+")
                                                                                                                                            #!/usr/bin/python3
fo.close()
                   Close opened file
                                                                                                    Open a file
                                                           fo.read(10)
                                        is
                                        str)
```

This produces the following result-

```
Read String
 ••
 Python is
```

#### **File Positions**

read or write will occur at that many bytes from the beginning of the file. The tell() method tells you the current position within the file; in other words, the next

The seek(offset[, from]) method changes the current file position. The offset argument indicates the number of bytes to be moved. The from argument specifies the reference position from where the bytes are to be moved.

the file would be taken as the reference position. If *from* is set to 0, the beginning of the file is used as the reference position. If it is set to 1, the current position is used as the reference position. If it is set to 2 then the end of

#### Example

Let us take a file foo.txt, which we created above

#!/usr/bin/python3

```
print ("Again read String is
                                                                                                                                                                                                                  print ("Current file position : ", position)
                                                                                           str = fo.read(10)
                                                                                                                        position = fo.seek(0, 0)
                                                                                                                                                        # Reposition pointer at the beginning once again
                                                                                                                                                                                                                                                                                                                                               print ("Read String is : ", str)
fo.close()
                                                                                                                                                                                                                                                     position = fo.tell()
                                                                                                                                                                                                                                                                                                                                                                             str = fo.read(10)
                                                                                                                                                                                                                                                                                                                                                                                                          fo = open("foo.txt", "r+")
                                                                                                                                                                                                                                                                                  Check current position
                                                                                                                                                                                                                                                                                                                                                                                                                                          Open a file
                             Close opened file
                                                     . =
                                                            str)
```

This produces the following result-

```
Again read String is :
                       Current file position :

```

## Renaming and Deleting Files

Python **os** module provides methods such as renaming and deleting files. that help you perform file-processing operations,

To use this module, you need to import it first and then you can call any related functions

## The rename() Method

The rename() method takes two arguments, the current filename and the new filename.

#### Syntax

```
os.rename(current_file_name, new_file_name)
```

#### Example

Following is an example to rename an existing file test1.txt-

```
#!/usr/bin/python3
import os
```

```
os.rename( "test1.txt", "test2.txt"
                                       # Rename a
                                        file from test1.txt to test2.txt
```

## The remove() Method

You can use the remove() method to delete files by supplying the name of the file to be deleted as the argument.

#### Syntax

```
os.remove(file_name)
```

#### Example

Following is an example to delete an existing file test2.txt-

```
os.remove("text2.txt")
                                   # Delete file test2.txt
                                                                                                                                      #!/usr/bin/python3
```

## Directories in Python

too. The  ${f os}$  module has several methods that help you create, remove, and change directories. All files are contained within various directories, and Python has no problem handling these

## The mkdir() Method

the directory to be created. directory. You need to supply an argument to this method, which contains the name of You can use the mkdir() method of the **os** module to create directories in the current

#### Syntax

```
os.mkdir("newdir")
```

#### Example

Following is an example to create a directory test in the current directory-

```
import os
                     #!/usr/bin/python3
```

```
os.mkdir("test")
                         Create a directory "test"
```

## The chdir() Method

You can use the chdir() method to change the current directory. The chdir() method takes an argument, which is the name of the directory that you want to make the current directory.

#### Syntax

```
os.chdir("newdir")
```

#### Example

Following is an example to go into "/home/newdir" directory-

```
os.chdir("/home/newdir")
                                 # Changing a directory to "/home/newdir"
                                                                                                                                       #!/usr/bin/python3
                                                                                                       import os
```

## The getcwd() Method

The getcwd() method displays the current working directory.

#### Syntax

```
os.getcwd()
```

#### Example

Following is an example to give current directory-

```
# This would give location of the current directory
                                                                                                            import os
                                                                                                                                            #!/usr/bin/python3
os.getcwd()
```

## The rmdir() Method

The rmdir() method deletes the directory, which is passed as an argument in the method.

Before removing a directory, all the contents in it should be removed.

#### Syntax

```
os.rmdir('dirname')
```

#### Example

qualified name of the directory, otherwise it would search for that directory in the current directory. Following is an example to remove the "/tmp/test" directory. It is required to give fully

```
# This would
                                                                           import os
                                                                                                 #!/usr/bin/python3
os.rmdir( "/tmp/test"
                         remove "/tmp/test"
                        directory.

# File & Directory Related Methods

and manipulate files & directories on Windows and Unix operating systems. They are as There are three important sources, which provide a wide range of utility methods to handle

- File Object Methods: The file object provides functions to manipulate files
- OS Object Methods: This provides methods to process files as well as directories.

#### File Methods

A **file** object is created using open function and here called on this object. S. а list of functions which can be

2   <b>fil</b>	Clo	1 file	No.
file.flush()	Close the file. A closed file cannot be read or written any more.	file.close()	Methods with Description

11			9	8	7	6	G	4	ω	
file.truncate([size])  Truncates the file's size. If the optional size argument is present, the file is truncated to (at most) that size.  file.write(str)	optional size argument is present, the	optional size argument is present, the	<pre>file.seek(offset[, whence]) Sets the file's current position</pre>	file.readlines([sizehint])  Reads until EOF using readline() and return a list containing the lines. If the optional sizehint argument is present, instead of reading up to EOF, whole lines totalling approximately sizehint bytes (possibly after rounding up to an internal buffer size) are read.	<b>file.readline([size])</b> Reads one entire line from the file. A trailing newline character is kept in the string.	file.read([size]) Reads at most size bytes from the file (less if the read hits EOF before obtaining size bytes).	<b>next(file)</b> Returns the next line from the file each time it is being called.	<b>file.isatty()</b> Returns True if the file is connected to a tty(-like) device, else False.	<b>file.fileno()</b> Returns the integer file descriptor that is used by the underlying implementation to request I/O operations from the operating system.	Flush the internal buffer, like stdio's fflush. This may be a no-op on some file-like objects.

	13	
Writes a sequence of strings to the file. The sequence can be any iterable object producing strings, typically a list of strings.	file.writelines(sequence)	Writes a string to the file. There is no return value.

Let us go through the above mentions methods briefly.

### File close() Method

#### Description

The method **close()** closes the opened file. A closed file cannot be read or written any more. Any operation, which requires that the file be opened will raise a ValueError after the file has been closed. Calling close() more than once is allowed.

another file. It is a good practice to use the close() method to close a file. Python automatically closes a file when the reference object of a file is reassigned to

#### Syntax

Following is the syntax for close() method-

```
fileObject.close()
```

#### **Parameters**

Z

#### **Return Value**

This method does not return any value.

#### Example

The following example shows the usage of close() method.

```
print ("Name of the file: ",
                                                                                                           #!/usr/bin/python3
                      # Close opened file
                                                                 fo = open("foo.txt",
                                                                                         # Open a file
fo.close()
                                                                    "wb")
                                            fo.name)
```

When we run the above program, it produces the following result-

```
Name of the file: foo.txt
```

### File flush() Method

#### Description

The method **flush()** flushes the internal buffer, like stdio's fflush. This may be a no-op on some file-like objects.

Python automatically flushes the files when closing them. But you may want to flush the data before closing any file.

#### Syntax

Following is the syntax for flush() method-

fileObject.flush()

#### **Parameters**

Z

#### **Return Value**

This method does not return any value.

#### Example

The following example shows the usage of flush() method.

```
print ("Name of the file: ", fo.name)
                                                                                                                                                                                                                                       #!/usr/bin/python3
                                # Close opend file
                                                                                                  # Here it does nothing, but you can call it with read operation.
                                                                                                                                                                   fo = open("foo.txt",
                                                                                                                                                                                                       # Open a file
fo.close()
                                                                  fo.flush()
                                                                                                                                                                       "wb")
```

When we run the above program, it produces the following result-

```
Name
of
the
file:
foo.txt
```

### File fileno() Method

#### **Description**

implementation to request I/O operations from the operating system. The method fileno() returns the integer file descriptor that is used by the underlying

#### Syntax

Following is the syntax for fileno() method-

```
fileObject.fileno()
```

#### **Parameters**

Z

#### **Return Value**

This method returns the integer file descriptor.

#### Example

The following example shows the usage of fileno() method.

```
print ("File Descriptor:
                                                                                    print ("Name of the file: ",
                                                                                                                                                       #!/usr/bin/python3
                                                                                                          fo = open("foo.txt",
                                                                                                                                  # Open a file
fo.close()
                    # Close opend file
                                                                 fid = fo.fileno()
                                                                                                             "wb")
                                    . =
                                                                                       fo.name)
```

When we run the above program, it produces the following result-

```
File Descriptor:
                 the
                foo.txt
```

### File isatty() Method

#### Description

The method isatty() returns True if the device) to a tty(-like) device, else False. file is connected (is associated with a terminal

#### Syntax

Following is the syntax for isatty() method-

```
fileObject.isatty()
```

#### **Parameters**

 $\stackrel{\sf N}{\succ}$ 

#### **Return Value**

a tty(-like) device, else false. This method returns true if the file is connected (is associated with a terminal device) to

#### Example

The following example shows the usage of isatty() method-

```
print ("Return value :
                                                                                            print ("Name of the file: ",
                                                                                                                    fo = open("foo.txt",
                                                                                                                                               # Open a file
                                                                                                                                                                      #!/usr/bin/python3
fo.close()
                                                                       ret = fo.isatty()
                       Close opend file
                                                                                                                      "wb")
                                                ret)
                                                                                               fo.name)
```

When we run the above program, it produces the following result-

```
Return value
              Name of
              the file:
..
False
              foo.txt
```

### File next() Method

#### **Description**

next() which retrieves the next item from the iterator by calling its \_\_next\_\_() method. If default is given, it is returned if the iterator is exhausted, otherwise StopIteration is raised. This method can be used to read the next input line, from the file object. File object in Python 3 does not support **next()** method. Python 3 has a built-in function \_next\_\_() method. If

#### Syntax

Following is the syntax for next() method-

```
next(iterator[,default])
```

#### **Parameters**

• iterator : file object from which lines are to be read

default: returned if iterator exhausted. If not given, StopIteration is raised

#### **Return Value**

This method returns the next input line.

#### Example

The following example shows the usage of next() method-

```
PP
          Per1
                                   Java
                                              C++
                       Python
                                                         Assuming
                                                           that
                                                           'foo.txt'
                                                           contains
                                                         following lines
```

```
print ("Name of the file: ",
                                                                                                                                                              #!/usr/bin/python3
                                                                              for index in range(5):
                                                                                                                     fo = open("foo.txt",
fo.close()
                                                                                                                                           Open a file
                    Close opened file
                                      print ("Line No %d
                                                            line = next(fo)
                                                                                                                      "r")
                                          ı
                                        %s"
                                       % (index, line))
                                                                                                    fo.name)
```

When we run the above program, it produces the following result-

```

### File read() Method

#### Description

obtaining size bytes, then it reads only available bytes. The method read() reads at most size bytes from the file. If the read hits EOF before

#### **Syntax**

Following is the syntax for read() method-

```
fileObject.read( size
\ddot{\cdot}
```

#### **Parameters**

size - This is the number of bytes to be read from the file.

#### **Return Value**

This method returns the bytes read in string.

#### Example

The following example shows the usage of read() method.

```
This
             This
                           This

                                                                  contains
                                                                 the following text:
```

```
print ("Read Line: %s"
                                                                             print ("Name of the file: ",
                                                                                                                                          #!/usr/bin/python3
                    # Close opened file
                                                                                                  fo = open("foo.txt",
fo.close()
                                                                                                                      Open a file
                                                          fo.read(10)
                                                                                                    "r+")
                                         %
                                         (line))
                                                                               fo.name)
```

When we run the above program, it produces the following result-

```
Name
٩
the
file:
foo.txt
```

```
Read

is
```

## File readline() Method

#### Description

count including the trailing newline and an incomplete line may be returned. The method readline()reads one entire line from the file. A trailing newline character is kept in the string. If the size argument is present and non-negative, it is a maximum byte

An empty string is returned only when EOF is encountered immediately.

#### Syntax

Following is the syntax for readline() method-

```
fileObject.readline(
size
```

#### **Parameters**

size - This is the number of bytes to be read from the file.

#### **Return Value**

This method returns the line read from the file.

#### Example

The following example shows the usage of readline() method.

Assuming that 'foo.txt' file contains following text-

```
This
                        This
                                This
                        15
is
        is
               is
                                is 1st
       4th
                        2nd
                3rd
5th line
        line
                        line
                               line
                line
```

```
line
                                                             print
                  print ("Read Line: %s"
                                                                                                      # Open a file
                                                                                                                           #!/usr/bin/python3
                                         line =
                                                                                fo = open("foo.txt",
                                                            ("Name of the file: ",
fo.readline(5)
                                        fo.readline()
                                                                                   "+")
                    % (line))
                                                            fo.name)
```

```
print ("Read Line:
fo.close()
                Close opened file
                                %s"
                                 %
```

When we run the above program, it produces the following result-

```
Read
                     Name
Read Line:
           Line: This
                     ٩
                     the
This
                     file:
           ż
           1st line
                     foo.txt
```

## File readlines() Method

#### **Description**

lines. If the optional sizehint argument is present, instead of reading up to EOF, whole lines totalling approximately sizehint bytes (possibly after rounding up to an internal buffer size) are read. The method readlines() reads until EOF using readline() and returns a list containing the

An empty string is returned only when EOF is encountered immediately.

#### Syntax

Following is the syntax for readlines() method-

```
fileObject.readlines( sizehint
```

#### **Parameters**

sizehint - This is the number of bytes to be read from the file.

#### **Return Value**

This method returns a list containing the lines

#### Example

The following example shows the usage of readlines() method.

### File seek() Method

#### Description

means seek relative to the current position and 2 means seek relative to the file's end. optional and defaults to 0, which means absolute file positioning, other values are 1 which The method seek() sets the file's current position at the offset. The whence argument is

'a+', any seek() operations will be undone at the next write. There is no return value. Note that if the file is opened for appending using either 'a' or

no-op, but it remains useful for files opened in append mode with reading enabled (mode If the file is only opened for writing in append mode using 'a', this method is essentially a

other offsets causes undefined behavior. If the file is opened in text mode using 't', only offsets returned by tell() are legal. Use of

Note that not all file objects are seekable.

#### Syntax

Following is the syntax for seek() method-

```
fileObject.seek(offset[,
  whence])
```

#### **Parameters**

- offset- This is the position of the read/write pointer within the file
- seek relative to the file's end. **whence**- This is optional and defaults to 0 which means absolute file positioning, other values are 1 which means seek relative to the current position and 2 means

#### **Return Value**

This method does not return any value.

#### Example

The following example shows the usage of seek() method.

```

                                                                                                                                                                                                                fo.readlines()
                                                                                                                                                                                                                                                                                     "rw+")
                                                                                                                                                                                          %
                                                                                                                                         to the beginning
                                                                                                                                                                                         (line))
                                                                                                                                                                                                                                                               fo.name)
```

When we run the above program, it produces the following result-

```
Read Line: ['This is 1st line\n', 'This 'This is 4th line\n', 'This is 5th line']
                                                                    Name
Read Line: This is 1st line
                                                                   of the file:
                                                                  foo.txt
                                      'This is
                                         2nd line\n',
                                           'This
                                           15
                                          3rd line\n',
```

### File tell() Method

#### **Description**

The method tell() returns the current position of the file read/write pointer within the file.

#### Syntax

Following is the syntax for tell() method-

```
fileObject.tell()
```

#### **Parameters**

Z

#### **Return Value**

This method returns the current position of the file read/write pointer within the file.

#### Example

The following example shows the usage of tell() method-

```
This
                                                         This is 2nd line
                                                                            This is 1st line
                                                                                               Assuming that 'foo.txt'
is
                  is 4th
                                     3rd
5th line
                  line
                                      line
                                                                                               file contains following text:
```

```
print ("current position :
                                                            print ("Read Line: %s" % (line))
                                                                                                                      print ("Name of the file: ",
                                                                                                                                                                                 #!/usr/bin/python3
                                pos=fo.tell()
                                                                                                                                                   fo = open("foo.txt", "r+")
                                                                                           fo.readline()
  ", pos)
                                                                                                                         fo.name)
```

```
fo.close()
                 Close opened
```

When we run the above program, it produces the following result-

```
Name
                                                   Read Line: This is 1st line
Current Position: 18
                                                                             of the file:
                                                                            foo.txt
```

## File truncate() Method

#### **Description**

The method **truncate()** truncates the file's size. If the optional size argument is present, the file is truncated to (at most) that size.

The size defaults to the current position. The current file position is not changed. Note that if a specified size exceeds the file's current size, the result is platform-dependent.

**Note**: This method will not work in case the file is opened in read-only mode.

#### Syntax

Following is the syntax for truncate() method-

```
fileObject.truncate(
size
```

#### **Parameters**

size - If this optional argument is present, the file is truncated to (at most) that size

#### **Return Value**

This method does not return any value.

#### Example

The following example shows the usage of truncate() method.

```

                                                                                                                                                                                                                                       fo =
                                                                                                                                                                                                                                                                                #!/usr/bin/python3
fo.close()
                                                                                    line = fo.readlines()
                                                                                                         fo.truncate()
                   Close opened file
                                                                                                                                                                         = fo.readline()
                                                                                                                                                                                                                                     open("foo.txt", "r+")
                                                                                                                                                     %
                                                             % (line))
                                                                                                                                                    (line))
                                                                                                                                                                                                                   fo.name)
```

When we run the above program, it produces the following result-

```
Name
Read Line: []
                     Read Line: This is 1s
                                        of the file:
                                        foo.txt
```

### File write() Method

#### **Description**

buffering, the string may not actually show up in the file until the flush() or close() method is called. The method write() writes a string str to the file. There is no return value. Due to

#### Syntax

Following is the syntax for write() method-

```
fileObject.write(
str
```

#### **Parameters**

**str** - This is the String to be written in the file.

#### **Return Value**

This method does not return any value.

#### Example

The following example shows the usage of write() method.

```
This
              This
                              This
                                                                         Assuming that 'foo.txt'
                                            is
              is 4th
                              is 3rd line
                                                            is 1st line

# File writelines() Method

### Description

any iterable object producing strings, typically a list of strings. There is no return value. The method writelines() writes a sequence of strings to the file. The sequence can be

#### Syntax

Following is the syntax for writelines() method –

```
fileObject.writelines( sequence
```

#### **Parameters**

sequence - This is the Sequence of the strings.

## **Return Value**

This method does not return any value.

#### Example

The following example shows the usage of writelines() method.

```

# **OS File/Directory Methods**

Most of the useful methods are listed here: The os module provides a big range of useful methods to manipulate files and directories.

No.

2	os.chdir(path)
	Change the current working directory to path
ω	os.chflags(path, flags)
	Set the flags of path to the numeric flags.
4	os.chmod(path, mode)
	Change the mode of path to the numeric mode.
б	os.chown(path, uid, gid)
	Change the owner and group id of path to the numeric uid and gid.
6	os.chroot(path)
	Change the root directory of the current process to path.
7	os.close(fd)
	Close file descriptor fd.
8	os.closerange(fd_low, fd_high)
	Close all file descriptors from fd_low (inclusive) to fd_high (exclusive), ignoring errors.
9	os.dup(fd)
	Return a duplicate of file descriptor fd.
10	os.dup2(fd, fd2)
	Duplicate file descriptor fd to fd2, closing the latter first if necessary.
11	os.fchdir(fd)

os.ftruncate(fd, length)	20
Force write of file with filedescriptor fd to disk.	
os.fsync(fd)	19
Return information about the filesystem containing the file associated with file descriptor fd, like statvfs().	
os.fstatvfs(fd)	18
Return status for file descriptor fd, like stat().	
os.fstat(fd)	17
Return system configuration information relevant to an open file. name specifies the configuration value to retrieve.	
os.fpathconf(fd, name)	16
Return an open file object connected to the file descriptor fd.	
os.fdopen(fd[, mode[, bufsize]])	15
Force write of file with filedescriptor fd to disk.	
os.fdatasync(fd)	14
Change the owner and group id of the file given by fd to the numeric uid and gid.	
os.fchown(fd, uid, gid)	13
Change the mode of the file given by fd to the numeric mode.	
os.fchmod(fd, mode)	12
Change the current working directory to the directory represented by the file descriptor fd.	

28		,	1	26		25		24		23		22		21	
Return a list containing the names of the entries in the directory given by path.	os.listdir(path)	Create a hard link pointing to src named dst.	Change the owner and group id of path to the numeric uid and gid. This function will not follow symbolic links.	os.lchown(path, uid, gid)	Change the mode of path to the numeric mode.	os.lchmod(path, mode)	Set the flags of path to the numeric flags, like chflags(), but do not follow symbolic links.	os.lchflags(path, flags)	Return True if the file descriptor fd is open and connected to a tty(-like) device, else False.	os.isatty(fd)	Return a Unicode object representing the current working directory.	os.getcwdu()	Return a string representing the current working directory.	os.getcwd()	Truncate the file corresponding to file descriptor fd, so that it is at most length bytes in size.

os.open(file, flags[, mode])	38
Create a filesystem node (file, device special file or named pipe) named filename.	
os.mknod(filename[, mode=0600, device])	37
Create a FIFO (a named pipe) named path with numeric mode mode. The default mode is 0666 (octal).	
os.mkfifo(path[, mode])	36
Create a directory named path with numeric mode mode.	
os.mkdir(path[, mode])	35
Extract the device minor number from a raw device number .	
os.minor(device)	34
Recursive directory creation function.	
os.makedirs(path[, mode])	33
Compose a raw device number from the major and minor device numbers.	
os.makedev(major, minor)	32
Extract the device major number from a raw device number.	
os.major(device)	31
Like stat(), but do not follow symbolic links.	
os.lstat(path)	30
Set the current position of file descriptor fd to position pos, modified by how.	

Remove directories recursively.	0	
Remove the file path.		
os.remove(path)	45	
Return a string representing the path to which the symbolic link points.		
os.readlink(path)	44	
Read at most n bytes from file descriptor fd. Return a string containing the bytes read. If the end of the file referred to by fd has been reached, an empty string is returned.		
os.read(fd, n)	43	
Open a pipe to or from command.		
os.popen(command[, mode[, bufsize]])	42	
Create a pipe. Return a pair of file descriptors (r, w) usable for reading and writing, respectively.		
os.pipe()	41	
Return system configuration information relevant to a named file.		
os.pathconf(path, name)	40	
Open a new pseudo-terminal pair. Return a pair of file descriptors (master, slave) for the pty and the tty, respectively.		
os.openpty()	39	-
Open the file file and set various flags according to flags and possibly its mode according to mode.		1

47	or rosamplero deto
1,	osii ciialiic(sic, usc)
	Rename the file or directory src to dst.
48	os.renames(old, new)
	Recursive directory or file renaming function.
49	os.rmdir(path)
	Remove the directory path
50	os.stat(path)
	Perform a stat system call on the given path.
51	os.stat_float_times([newvalue])
	Determine whether stat_result represents time stamps as float objects.
52	os.statvfs(path)
	Perform a statvfs system call on the given path.
53	os.symlink(src, dst)
	Create a symbolic link pointing to src named dst.
54	os.tcgetpgrp(fd)
	Return the process group associated with the terminal given by fd (an open file descriptor as returned by open()).
55	os.tcsetpgrp(fd, pg)
	Set the process group associated with the terminal given by fd (an open file descriptor as returned by open()) to pg.
56	os.tempnam([dir[, prefix]])

	Return a unique path name that is reasonable for creating a temporary file.
57	os.tmpfile()
	Return a new file object opened in update mode (w+b).
58	os.tmpnam()
	Return a unique path name that is reasonable for creating a temporary file.
59	os.ttyname(fd)
	Return a string which specifies the terminal device associated with file descriptor fd. If fd is not associated with a terminal device, an exception is raised.
60	os.unlink(path)
	Remove the file path.
61	os.utime(path, times)
	Set the access and modified times of the file specified by path.
62	os.walk(top[, topdown=True[, onerror=None[, followlinks=False]]])
	Generate the file names in a directory tree by walking the tree either top-down or bottom-up.
63	os.write(fd, str)
	Write the string str to file descriptor fd. Return the number of bytes actually written.

Let us go through the methods briefly-

## os.access() Method

## **Description**

use the effective uid/gid, therefore this routine can be used in a suid/sgid environment to test if the invoking user has the specified access to path.It returns True if access is allowed, False if not. The method access() uses the real uid/gid to test for access to path. Most operations will

#### Syntax

Following is the syntax for access() method-

```
os.access(path,
mode)
```

### **Parameters**

- path This is the path which would be tested for existence or any access
- ${\bf mode}$  - This should be F\_OK to test the existence of path, or it can be the inclusive OR of one or more of R\_OK, W\_OK, and X\_OK to test permissions.
- 0 of path. os.F\_OK: Value to pass as the mode parameter of access() to test the existence
- 0 readability of path. os.R\_OK: Value to include Ξ. the mode parameter of access() to test the
- 0 writability of path. os.W\_OK: Value to include in the mode parameter of access() to test the
- 0 os.X\_OK: Value to include in the mode parameter of access() to determine path can be executed.

## Return Value

This method returns True if access is allowed, False if not.

#### Example

The following example shows the usage of access() method

```
print
                                ret
                                                                                                                         ret = os.access("/tmp/foo.txt", os.F_OK)
                                                                                                                                                                                                                           #!/usr/bin/python3
                                                                                               print ("F_OK -
                                                                                                                                                                                           import os,
                                                                                                                                                            Assuming /tmp/foo.txt exists and has read/write permissions
("R_OK -
                                os.access("/tmp/foo.txt", os.R_OK)
                                                                                                return value %s"% ret)
   return
  value %s"% ret)
```

```
print
                       ret
                                                                                      ret
                                                                 print ("W_OK -
("X_0K
                    os.access("/tmp/foo.txt", os.X_OK)
                                                                                      os.access("/tmp/foo.txt", os.W_OK)
                                                                 return value %s"% ret)
 return

            True
                       True
                                     True
```

## os.chdir() Method

### Description

None in all the cases. The method chdir() changes the current working directory to the given path.It returns

#### Syntax

Following is the syntax for chdir() method-

```
os.chdir(path)
```

#### **Parameters**

path - This is complete path of the directory to be changed to a new location.

## **Return Value**

is not found. This method does not return any value. It throws FileNotFoundError if the specified path

#### Example

The following example shows the usage of chdir() method

```
#
                                                       # Now change the directory
                                                                                   path = "d:\\python3" #change path for linux
                              os.chdir( path )
                                                                                                                  import os
                                                                                                                                             #!/usr/bin/python3
Check current working
  directory.
```

```
print ("Directory changed
                retval
                П
               os.getcwd()
successfully
 %s"
 %
 retval)
```

Directory changed successfully d:\python3

## os.chflags() Method

### Description

combination (bitwise OR) of the various values described below The method **chflags()** sets the flags of path to the numeric flags. The flags may take а

changed by super-user only. Note: This method is available Python version 2.6 onwards. Most of the flags can be

#### Syntax

Following is the syntax for chflags() method-

os.chflags(path, flags)

## **Parameters**

- **path** This is a complete path of the directory to be changed to a new location.
- flags The flags specified are formed by OR'ing the following values-
- os.UF\_NODUMP: Do not dump the file.
- os.UF\_IMMUTABLE: The file may not be changed.
- os.UF\_APPEND: The file may only be appended to.
- 0 os.UF\_NOUNLINK: The file may not be renamed or deleted.
- 0 os.UF\_OPAQUE: The directory is opaque when viewed through a union stack.
- os.SF\_ARCHIVED: The file may be archived.
- os.SF\_IMMUTABLE: The file may not be changed.
- os.SF\_APPEND: The file may only be appended to
- os.SF\_NOUNLINK: The file may not be renamed or deleted.
- os.SF\_SNAPSHOT: The file is a snapshot file.

## Return Value

This method does not return any value

#### Example

The following example shows the usage of chflags() method.

```
print ("Return Value: %s"
                                                                   # Set a
                                                                                     path = "/tmp/foo.txt"
                                                                                                                             #!/usr/bin/python3
                    retval = os.chflags( path,
                                                                                                           import
                                                                                                           20
                                          os.SF_NOUNLINK
                                                                flag so that file
  % retval)
                                                                  may not be
                      flags)
                                                                  renamed or
                                                                  deleted.
```

When we run the above program, it produces the following result-

```
Value
None
```

## os.chmod() Method

## Description

may take one of the following values or bitwise ORed combinations of them-The method chmod() changes the mode of path to the passed numeric mode. The mode

- stat.S\_ISUID: Set user ID on execution.
- stat.S\_ISGID: Set group ID on execution.
- stat.S\_ENFMT: Record locking enforced
- stat.S\_ISVTX: Save text image after execution.
- stat.S\_IREAD: Read by owner.
- stat.S\_IWRITE: Write by owner.
- stat.S\_IEXEC: Execute by owner.
- stat.S\_IRWXU: Read, write, and execute by owner.
- stat.S\_IRUSR: Read by owner.
- stat.S\_IWUSR: Write by owner.
- stat.S\_IXUSR: Execute by owner.
- stat.S\_IRWXG: Read, write, and execute by group.
- stat.S\_IRGRP: Read by group.
- stat.S\_IWGRP: Write by group.

- stat.S\_IXGRP: Execute by group.
- stat.S\_IRWXO: Read, write, and execute by others.
- stat.S\_IROTH: Read by others.
- stat.S\_IWOTH: Write by others.
- stat.S\_IXOTH: Execute by others.

#### Syntax

Following is the syntax for chmod() method-

```
os.chmod(path, mode)
```

#### **Parameters**

- path This is the path for which mode would be set.
- mode combinations of them. This may take one of the above mentioned values or bitwise ORed

## **Return Value**

This method does not return any value

All other bits are ignored. it (via the stat.S\_ **Note:** Although Windows supports chmod(), you can only set the file's read-only flag with it (via the stat.S\_IWRITE and stat.S\_IREAD constants or a corresponding integer value).

#### Example

The following example shows the usage of chmod() method-

```
print
                                                      os.chmod("/tmp/foo.txt", stat.S_IWOTH)
                                                                                                                                os.chmod("/tmp/foo.txt", stat.S
                                                                                                                                                                                                                                      import os,
                                                                                                                                                                                                                                                                 #!/usr/bin/python3
                                                                                                                                                                                     Assuming /tmp/foo.txt exists,
  ("Changed mode
                                                                                 a file write
                                                                                                                                                                                                                                      sys, stat
                                                                               by others
successfully!!")
                                                                                                                                    _IXGRP)
                                                                                                                                                                                      Set a
                                                                                                                                                                                     file execute by the group.
```

Changed mode successfully!!

## os.chown() Method

#### **Description**

user privilege.. The method **chown()** changes the owner and group id of path to the numeric uid and gid. To leave one of the ids unchanged, set it to -1.To set ownership, you would need super

#### **Syntax**

Following is the syntax for chown() method-

```
os.chown(path, uid, gid)
```

### **Parameters**

- path This is the path for which owner id and group id need to be setup.
- **uid** This is Owner ID to be set for the file.
- **gid** This is Group ID to be set for the file.

## **Return Value**

This method does not return any value.

#### Example

The following example shows the usage of chown() method

```
os.chown("/tmp/foo.txt", 100,
print ("Changed ownership successfully!!")
                                                                                                                                                                    import os,
                                                                                                                                                                                                             #!/usr/bin/python3
                                                                                  To set owner ID 100 following has to be done.
                                                                                                                        Assuming /tmp/foo.txt exists.
```

When we run the above program, it produces the following result-

Changed ownership successfully!!

## os.chroot() Method

## Description

privilege. Available on Unix like systems only. To use this method, you would need super user The method chroot() changes the root directory of the current process to the given path.

#### Syntax

Following is the syntax for chroot() method-

```
os.chroot(path)
```

### **Parameters**

path - This is the path which would be set as root for the current process

## **Return Value**

This method does not return any value

#### Example

The following example shows the usage of chroot() method.

```
print ("Changed root path successfully!!")
                                   os.chroot("/tmp/usr")
                                                                          # To set the current root path to /tmp/user
                                                                                                              import os,
                                                                                                                                                 #!/usr/bin/python3
                                                                                                              sys
```

When we run the above program, it produces the following result-

```
Changed root path successfully!!
```

# Python os.close() Method

## Description

The method close() closes the associated with file descriptor fd.

#### Syntax

Following is the syntax for close() method

```
os.close(fd)
```

## **Parameters**

fd - This is the file descriptor of the file.

## Return Value

This method does not return any value.

**Note:** This function is intended for low-level I/O and must be applied to a file descriptor as returned by os.open() or pipe().

#### Example

The following example shows the usage of close() method.

```
os.write(fd, b)
                                                                                                                                                           # string needs to be converted byte object
print ("Closed the file successfully!!")
                              os.close( fd )
                                                                                                                               b=str.encode(line)
                                                                                                                                                                                            line="this is test"
                                                                                                                                                                                                                            # Write one string
                                                                                                                                                                                                                                                        fd = os.open( "foo.txt",
                                                                                                                                                                                                                                                                                            # Open a file
                                                                                                                                                                                                                                                                                                                                                            #!/usr/bin/python3
                                                                                                                                                                                                                                                                                                                            import os,
                                                               Close opened file
                                                                                                                                                                                                                                                            os.O_RDWR|os.O_CREAT )
```

When we run the above program, it produces the following result-

Closed

the

file

successfully!!

# os.closerange() Method

### Description

The method closerange() closes all file descriptors from fd\_low (inclusive) to fd\_high (exclusive), ignoring errors. This method is introduced in Python version 2.6.

#### Syntax

Following is the syntax for closerange() method-

```
os.closerange(fd_low,
  fd_high)
```

#### **Parameters**

- fd\_low This is the Lowest file descriptor to be closed.
- fd\_high This is the Highest file descriptor to be closed.

This function is equivalent to-

```
for fd in xrange(fd_low, fd_high):
                                                                     try:
                      except OSError:
pass
                                             os.close(fd)
```

## **Return Value**

This method does not return any value.

#### Example

The following example shows the usage of closerange() method

```
print ("Closed all the files successfully!!")
                                                                   os.closerange( fd, fd)
                                                                                                                                             os.write(fd, b)
                                                                                                                                                                                 b=str.encode(line)
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                import os, sys
                                                                                                                                                                                                                       # string needs to be converted byte object
                                                                                                                                                                                                                                                          line="this is test"
                                                                                                                                                                                                                                                                                               # Write one string
                                                                                                                                                                                                                                                                                                                                                                                                             # Open a file
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        #!/usr/bin/python3
                                                                                                                                                                                                                                                                                                                                                                      fd = os.open( "foo.txt", os.0_RDWR|os.0_CREAT )
                                                                                                          Close a single opened file
```

This would create given file foo.txt and then write given content in that file. produce the following result-This will

```
Closed all the files successfully!
```

## os.dup() Method

### **Description**

original descriptor. The method dup() returns a duplicate of file descriptor fd which can be used in place of

#### Syntax

Following is the syntax for dup() method-

```
os.dup(fd)
```

### **Parameters**

fd - This is the original file descriptor.

## Return Value

This method returns a duplicate of file descriptor.

#### Example

The following example shows the usage of dup() method-

```
os.closerange( fd, d_fd)
                              # Close a single opened file
                                                                                                                                                      b=str.encode(line)
                                                                                                                                                                                                                    line="this is test"
                                                                                                                                                                                                                                                                                                                                               d_fd = os.dup(fd)
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    import os, sys
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    #!/usr/bin/python3
                                                                                           os.write(d_fd, b)
                                                                                                                                                                                      # string needs to be
                                                                                                                                                                                                                                                                                  # Write one string using duplicate fd
                                                                                                                                                                                                                                                                                                                                                                               # Get one duplicate file
                                                                                                                                                                                                                                                                                                                                                                                                                                                                        # Open a
                                                                                                                                                                                                                                                                                                                                                                                                                                           fd = os.open( "foo.txt", os.0_RDWR|os.0_CREAT )
                                                                                                                                                                                                                                                                                                                                                                                                                                                                            file
                                                                                                                                                                                       converted byte object
                                                                                                                                                                                                                                                                                                                                                                               descriptor
```

```
print "Closed all the files successfully!!"
```

```
Closed all the files successfully!!
```

## os.dup2() Method

### **Description**

The method dup2() duplicates file descriptor fd to fd2, closing the latter first if necessary.

**Note:** New file description would be assigned only when it is available. In the following example given below, 1000 would be assigned as a duplicate fd in case when 1000 is available.

#### Syntax

Following is the syntax for dup2() method-

```
os.dup2(fd,
 fd2)
```

#### **Parameters**

- fd This is File descriptor to be duplicated.
- fd2 This is Duplicate file descriptor.

## **Return Value**

This method returns a duplicate of file descriptor.

#### Example

The following example shows the usage of dup2() method.

```
fd =
b=str.encode(line)
                                                                                                                     #
                                                                                                                                                                                                           # Open a file
                                                                                                                                                                                                                                                                   #!/usr/bin/python3
                                                          line="this is test"
                                                                                                                                                                                                                                      import os, sys
                              string needs
                                                                                                                    Write one string using duplicate fd

## os.fchdir() Method

### Description

The method **fchdir()** change the current working directory to the directory represented by the file descriptor fd. The descriptor must refer to an opened directory, not an open

#### **Syntax**

Following is the syntax for fchdir() method-

```
os.fchdir(fd)
```

### **Parameters**

fd - This is Directory descriptor.

## **Return Value**

This method does not return any value.

#### Example

The following example shows the usage of fchdir() method.

```
print ("Current working dir
                                                                                                                                                                                                                                                                                                                                                                                                                                   os.chdir("/var/www/html"
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      #!/usr/bin/python3

                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              sys
                              directory.
                                                                                   : %s"
                                                                                                                                                                                                                                                                                                                                                   %
                                                                                      %
                                                                                     os.getcwd())
                                                                                                                                                                                                                                                                                                                                             os.getcwd())
```

When we run the above program, it produces the following result-

```
Current working dir :
                 Current
                working
                 dir
/tmp
                 /var/www/html
```

## os.fchmod() Method

## **Description**

The method fchmod() changes the mode of the file given by fd to the numeric mode. The mode may take one of the following values or bitwise ORed combinations of them-

**Note:** This method is available Python 2.6 onwards.

- stat.S\_ISUID: Set user ID on execution.
- stat.S\_ISGID: Set group ID on execution.
- stat.S\_ENFMT: Record locking enforced.

- stat.S\_ISVTX: Save text image after execution.
- stat.S\_IREAD: Read by owner.
- stat.S\_IWRITE: Write by owner.
- stat.S\_IEXEC: Execute by owner.
- stat.S\_IRWXU: Read, write, and execute by owner.
- stat.S\_IRUSR: Read by owner.
- stat.S\_IWUSR: Write by owner.
- stat.S\_IXUSR: Execute by owner.
- stat.S\_IRWXG: Read, write, and execute by group.
- stat.S\_IRGRP: Read by group.
- stat.S\_IWGRP: Write by group.
- stat.S\_IXGRP: Execute by group.
- stat.S\_IRWXO: Read, write, and execute by others.
- stat.S\_IROTH: Read by others.
- stat.S\_IWOTH: Write by others.
- stat.S\_IXOTH: Execute by others.

#### Syntax

Following is the syntax for fchmod() method-

```
os.fchmod(fd, mode)
```

### **Parameters**

- fd This is the file descriptor for which mode would be set.
- combinations of them. mode This may take one of the above mentioned values or bitwise ORed

## **Return Value**

This method does not return any value. Available on Unix like operating systems only.

#### Example

The following example shows the usage of fchmod() method-

```
print ("Changed mode successfully!!")
                                                                                                                                                                                                                                                                                                                                                          # Now open a file "/tmp/foo.txt"
                                                                                                                                                                                                                                                                                                                                                                                                                #!/usr/bin/python3
os.close( fd
                                                                                                                                       os.fchmod(fd,
                                                                                                                                                                                                                       os.fchmod( fd,
                                                                                                                                                                                                                                                                                                                               fd = os.open( "/tmp", os.0_RDONLY )
                                                                                                                                                                                                                                                                                                                                                                                      import os,
                           Close opened
                                                                                                                                                                                                                                                                              മ
                                                                                                                                                                a file write by others.
                                                                                                                                                                                                                                                                          file execute by the group.
                                                                                                                                                                                                                                                                                                                                                                                    sys, stat
                                                                                                                                     stat.S_IWOTH)
                             file.
                                                                                                                                                                                                                       stat.S_IXGRP)
```

When we run the above program, it produces the following result-

Changed mode successfully!!

## os.fchown() Method

## **Description**

The method fchown() changes the owner and group id of the file given by fd to the numeric uid and gid. To leave one of the ids unchanged, set it to -1.

**Note:**This method is available Python 2.6 onwards.

#### Syntax

Following is the syntax for fchown() method-

```
os.fchown(fd,
 uid,
gid)
```

### **Parameters**

- fd This is the file descriptor for which owner id and group id need to be set up.
- uid This is Owner ID to be set for the file.

• **gid** - This is Group ID to be set for the file.

## **Return Value**

This method does not return any value. Available in Unix like operating systems only.

#### Example

The following example shows the usage of fchown() method

```
print ("Changed ownership successfully!!")
                                                                                                                                                                                                                                                                                                                                                                                                                                    # Now open a file "/tmp/foo.txt"
                                       # Close opened file.
                                                                                                                                                                                                                                                                                                               os.fchown( fd, 100, -1)
                                                                                                                                                                                                                                                                                                                                                         # Set the user Id to 100 for this file.
                                                                                                                                                                                                                                                                                                                                                                                           fd = os.open( "/tmp", os.O_RDONLY
                                                                                                                                                                                                                                                                                                                                                                                                                                                                           import os,
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    #!/usr/bin/python3
os.close( fd )
                                                                                                                                                                                              os.fchown( fd, -1, 50)
                                                                                                                                                                                                                                     Set the group Id to 50 for this file.
                                                                                                                                                                                                                                                                                                                                                                                                                                                                         sys, stat
```

When we run the above program, it produces the following result-

Changed ownership successfully!!

# os.fdatasync() Method

### Description

force update of metadata. If you want to flush your buffer then you can use this method. The method fdatasync() forces write of file with filedescriptor fd to disk. This does not

#### Syntax

Following is the syntax for fdatasync() method-

```
os.fdatasync(fd)
```

#### **Parameters**

fd - This is the file descriptor for which data to be written.

## **Return Value**

This method does not return any value.

#### Example

The following example shows the usage of fdatasync() method-

```
print ("Closed the file successfully!!")
                                                                                                                                                                             print ("Read String is
                                                                                                                                                                                                                                                                                                                      os.lseek(fd, 0, 0)
                                                                                                                                                                                                                                                                                                                                                                                                                              os.fdatasync(fd)
                                                                                                                                                                                                                                                                                                                                                                                                                                                               # Infact here you would not be able to see its effect.
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                 # Now you can use fdatasync() method.
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     os.write(fd, b)
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       b=str.encode(line)
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              # Write one string
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      import os, sys

                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   fd = os.open( "foo.txt", os.0_RDWR|os.0_CREAT )
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        # Open a file
                                                                       os.close( fd )
                                                                                                        Close opened file
                                                                                                                                                                         ", str)
```

When we run the above program, it produces the following result-

```
Read String
Closed the file successfully!!
                     is
                     This is test
```

## os.fdopen() Method

## Description

you can perform all the defined functions on file object. The method fdopen() returns an open file object connected to the file descriptor fd. Then

#### Syntax

Following is the syntax for fdopen() method-

```
os.fdopen(fd,
mode[,
bufsize]]);
```

#### **Parameters**

- fd This is the file descriptor for which a file object is to be returned.
- **mode** This optional argument is a string indicating how the file is to be opened. The most commonly-used values of mode are 'r' for reading, 'w' for writing (truncating the file if it already exists), and 'a' for appending.
- unbuffered, 1 means line buffered, any other positive value means use a buffer of bufsize - This optional argument specifies the file's desired buffer size: 0 means (approximately) that size.

## **Return Value**

This method returns an open file object connected to the file descriptor.

#### Example

The following example shows the usage of fdopen() method

```
print
                                                                                                                                    #
                                                                                                                                                                                                                              #!/usr/bin/python3
fo.write( "Python
                   # Write one string
                                                                                                                                                                      fd = os.open( "foo.txt",
                                                                                                                                                                                                             import os,
                                                                                                                                                                                         Open a file

# os.fpathconf() Method

### Description

The method **fpathconf()** returns system configuration information relevant to an open file. This variable is very similar to unix system call fpathconf() and accept the similar arguments.

#### Syntax

Following is the syntax for fpathconf() method-

```
os.fpathconf(fd,
 name)
```

### **Parameters**

- ${f fd}$  This is the file descriptor for which system configuration information is returned. to be
- **name** This specifies the configuration value to retrieve; it may be a string, which is the name of a defined system value; these names are specified in a number of

operating system are given in the os.pathconf\_names dictionary. standards (POSIX.1, Unix 95, Unix 98, and others). The names known to the host

## **Return Value**

This method returns system configuration information relevant to an open file

#### Example

The following example shows the usage of fpathconf() method

```
print
                                                                                                                      print ("Maximum length of a filename :%d"
                                                                                                                                                                                                                                                                                                            print ("%s" % os.pathconf_names)
 print ("Closed
                                                                                                                                                                                  # Now get maximum length of a filename
                                                                                                                                                                                                                                             no = os.fpathconf(fd, 'PC_LINK_MAX')

```

## os.fstat() Method

## Description

structure returned by fstat method-The method fstat() returns information about а file associated with the fd. Here S

st\_dev: ID of device containing file

st\_ino: inode number

st\_mode: protection

st\_nlink: number of hard links

st\_uid: user ID of owner

st\_gid: group ID of owner

st\_rdev: device ID (if special file)

st\_size: total size, in bytes

st\_blksize: blocksize for filesystem I/O

st\_blocks: number of blocks allocated

st\_atime: time of last access

st\_mtime: time of last modification

st\_ctime: time of last status change

#### Syntax

Following is the syntax for fstat() method-

os.fstat(fd)

### **Parameters**

fd - This is the file descriptor for which system information is to be returned.

## **Return Value**

This method returns information about a file associated with the fd

#### Example

The following example shows the usage of chdir() method.

#!/usr/bin/python3

```
print
                                                                                                              print
                                                                                                                                                                     print
                                                                                                                                                                                                                            # Now get
                                                                                                                                                                                                                                                fd =
                                                                                                                                                                                                                                                                                   import
os.close(fd)
                                                                                                                                                                                                                                                                  # Open a file
                                                                           # Now

## os.fstatvfs() Method

### **Description**

associated with file descriptor fd. The method fstatvfs() returns information about the file system containing This returns the following structurethe file

f\_bsize: file system block size

f\_frsize: fragment size

f\_blocks: size of fs in f\_frsize units

f\_bfree: free blocks

f\_bavail: free blocks for non-root

f\_files: inodes

```
    f_ffree: free inodes
```

f\_favail: free inodes for non-root

```
    f_fsid: file system ID
```

f\_flag: mount flags

f\_namemax: maximum filename length

#### **Syntax**

Following is the syntax for fstatvfs() method-

```
os.fstatvfs(fd)
```

### **Parameters**

fd - This is the file descriptor for which system information is to be returned

## **Return Value**

This method returns information about the file system containing the file associated.

#### Example

The following example shows the usage of fstatvfs() method.

```
print
                                                                                                                  print
# Now get
                                                                                                                                                                  info
                                                                                                                                                                                                                                                                                                                             #!/usr/bin/python3
                                                                                                                                                                                      # Now get
                                                                                                                                                                                                                                                          # Open a file
                                                                                                                                                                                                                                                                                                       import os, sys

## os.fsync() Method

### **Description**

The method fsync() forces write of file with file descriptor fd to disk. If you're starting with a Python file object f, first do f.flush(), and then do os.fsync(f.fileno()), to ensure that all internal buffers associated with f are written to disk.

#### Syntax

Following is the syntax for fsync() method-

```
os.fsync(fd)
```

## **Parameters**

fd - This is the file descriptor for buffer sync is required.

## **Return Value**

This method does not return any value.

#### Example

The following example shows the usage of fsync() method.

```
# Open a file
# Write one string
                         fd = os.open( "foo.txt",
                                                                           import os,
                                                                                                     #!/usr/bin/python3
                                                                           sys
                          os.O_RDWR|os.O_CREAT )
```

```
print ("Read String is
                                                                                                                                                                                                                                                # Now you can use
                        os.close( fd )
                                                # Close opened file
                                                                                                 b=line.decode()
                                                                                                                        line = os.read(fd, 100)
                                                                                                                                                  os.lseek(fd, 0,

# os.ftruncate() Method

### Description

at most length bytes in size. The method ftruncate() truncates the file corresponding to file descriptor fd, so that it is

#### Syntax

Following is the syntax for ftruncate() method-

```
os.ftruncate(fd, length)
```

#### **Parameters**

- fd This is the file descriptor, which needs to be truncated.
- length This is the length of the file where file needs to be truncated.

## **Return Value**

This method does not return any value. Available on Unix like systems

#### Example

The following example shows the usage of ftruncate() method.

```
print
                                                                                                                  print ("Read String is : ", str)
                                                                                                                                                                         os.lseek(fd, 0, 0)
                                                                                                                                                                                                     # Now read this file from the beginning
                                                                                                                                                                                                                                                                                                                                                                              # Write one string
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                               import os, sys
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                           #!/usr/bin/python3
                             os.close(fd)
                                                          # Close opened file
                                                                                                                                                  str =

```

## os.getcwd() Method

### Description

The method getcwd() returns current working directory of a process.

#### Syntax

Following is the syntax for getcwd() method-

```
os.ggetcwd(path)
```

#### **Parameters**

Z

## **Return Value**

This method returns the current working directory of a process.

#### Example

The following example shows the usage of getcwd() method-

```
print ("Current working dir : %s" % os.getcwd())
                                                                                                                 # Print current working directory
                                                                                                                                                                                                    # Use os.fchdir() method to change the dir
                                                                                                                                                                                                                                                                                                                                                                                                           print ("Current working dir : %s" % os.getcwd())
                                                                                                                                                                                                                                                                                                                                                                                                                                                 # Print current working directory
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      # First go to the "/var/www/html" directory
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              import os,

                                                                                                                                                                 os.fchdir(fd)
                                                                                                                                                                                                                                                                                    fd = os.open( "/tmp", os.0_RDONLY )
                                                                                                                                                                                                                                                                                                                       # Now open a directory "/tmp"
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  os.chdir("/var/www/html" )
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                 sys
```

When we run the above program, it produces the following result-

```
Current working dir : /tmp
                  working
                     dir:
                    /var/www/html
```

# os.getcwdu() Method

## Description

The method getcwdu() returns directory. a unicode object representing the current working

#### Syntax

Following is the syntax for getcwdu() method-

```
os.getcwdu()
```

## **Parameters**

Ν

## **Return Value**

This method returns a unicode object representing the current working directory.

#### Example

The following example shows the usage of getcwdu() method.

```
print ("Current working dir : %s" % os.getcwdu())
                                                                                                                                                                                                                                                                                      # Use os.fchdir() method to change the dir
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                               print ("Current working dir : %s" % os.getcwdu())
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     # Print current working directory
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        os.chdir("/var/www/html" )
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             import os, sys
                                                                                                                                                                                                                                                                                                                                                                                                           # Now open a directory "/tmp"
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                         #!/usr/bin/python3
os.close( fd )
                                                                                                                                                                                                                                                os.fchdir(fd)
                                                                                                                                                                                                                                                                                                                                                                     fd = os.open( "/tmp", os.O_RDONLY )
                                                                                                                                                          Print current working directory
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             First go to the "/var/www/html" directory
                                   Close opened directory.
```

When we run the above program, it produces the following result-

```
Current working dir :
                           Current working dir : /var/www/html
 /tmp
```

# os.isatty() Method

## Description

The method isatty()returns True if the file descriptor fd is open and connected to a tty(-like) device, else False.

#### Syntax

Following is the syntax for isatty() method-

```
os.isatty( fd
```

## **Parameters**

fd -This is the file descriptor for which association needs to be checked

## **Return Value**

device, else False. This method returns True if the file descriptor fd is open and connected to a tty(-like)

#### Example

The following example shows the usage of isatty() method

```
print
                                                                                                          ret =
os.close(
                                                                                                                                                                                            b=line.encode()

                                                               ret)
```

When we run the above program, it produces the following result-

Returned value is: False

# os.lchflags() Method

## Description

os.chflags(path, flags, follow\_symlinks=False). follow symbolic links unlike chflags() method. As of Python 3.3, this is equivalent to The method lchflags() sets the flags of path to the numeric flags. This method does not

Here, flags may take a combination (bitwise OR) of the following values (as defined in the stat module):

- UF\_NODUMP: Do not dump the file.
- UF\_IMMUTABLE: The file may not be changed.
- UF\_APPEND: The file may only be appended to
- UF\_NOUNLINK: The file may not be renamed or deleted
- UF\_OPAQUE: The directory is opaque when viewed through a union stack.
- SF\_ARCHIVED: The file may be archived.
- SF\_IMMUTABLE: The file may not be changed.
- SF\_APPEND: The file may only be appended to.
- PSF \_NOUNLINK: The file may not be renamed or deleted.
- SF\_SNAPSHOT: The file is a snapshot file.

**Note:** This method has been introduced in Python 2.6

#### Syntax

Following is the syntax for lchflags() method-

```
os.lchflags(path, flags)
```

## **Parameters**

- path This is the file path for which flags to be set.
- flags -This could be a combination (bitwise OR) of the above defined flags values.

## **Return Value**

This method does not return any value. Available on Unix like systems.

#### Example

The following example shows the usage of lchflags() method

```
print
                                                                                                                                                                                                 fd =
                                                                                                                                                  # Close opened
                                                   ret =
                                                                         # Now change the file flag.
                                                                                                                         os.close( fd )
                                                                                                                                                                                                                          path = "/var/www/html/foo.txt"
                                                                                                                                                                                                                                                                                                 import os,
                                                                                                                                                                                                                                                                                                                                                 #!/usr/bin/python3

```
Changed file flag successfully!!
```

# os.lchown() Method

## Description

The method Ichown() changes the owner and group id of path to the numeric uid and gid. This function will not follow symbolic links. To leave one of the ids unchanged, set it to -1. As of Python 3.3, this is equivalent to os.chown(path, uid, gid, follow\_symlinks=False).

#### Syntax

Following is the syntax for Ichown() method-

```
os.lchown(path, uid,
gid)
```

### **Parameters**

- path This is the file path for which ownership to be set.
- uid This is the Owner ID to be set for the file.
- gid This is the Group ID to be set for the file.

# **Return Value**

This method does not return any value.

#### Example

The following example shows the usage of Ichown() method

```
print ("Changed ownership successfully!!")
                                                                                                                                                                                 os.lchown( path, 500, -1)
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          #!/usr/bin/python3
                                                                      os.lchown( path, -1, 500)
                                                                                                                                                                                                                        # Set a file owner ID
                                                                                                                                                                                                                                                                                                                                                                      # Close opened file
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                 path = "/var/www/html/foo.txt"
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   # Open a file
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     import os, sys
                                                                                                                                                                                                                                                                                                                                  os.close( fd )
                                                                                                                                                                                                                                                                                                                                                                                                                                          fd = os.open( path, os.0_RDWR|os.0_CREAT )
                                                                                                                                                                                                                                                      Now change the file ownership.
                                                                                                          Set a file group ID
```

When we run above program, it produces following result-

```
Changed ownership successfully!!
```

# os.link() Method

## Description

to create a copy of existing file. The method link() creates a hard link pointing to src named dst. This method is very useful

#### Syntax

Following is the syntax for link() method-

```
os.link(src,
 dst)
```

## **Parameters**

- src This is the source file path for which hard link would be created.
- dest This is the target file path where hard link would be created

## **Return Value**

This method does not return any value. Available on Unix, Windows

#### Example

The following example shows the usage of link() method.

```
print
                                                                                      # Now
                                                                                                                                                                                                                path = "d:\\python3\\foo.txt"
                                           os.link( path,
                                                                                                                               os.close(fd)
                                                                                                                                                                                                                                        # Open
                                                                                                                                                                                                                                                          import os, sys
                                                                                                                                                                                                                                                                                #!/usr/bin/python3
                                                                                                                                                                                           fd = os.open( path, os.0_RDWR|os.0_CREAT )
                                                                                                                                                   Close opened
("Created hard link
                                                               "d:\\tmp\\foo.txt"
                                                                                    create another copy

                                                                                                                                                                                                                                         file
                                             dst)
                                                                                                                                                     file
successfully!!")
                                                                                       ٩
                                                                                     the above
                                                                                      file.
```

When we run the above program, it produces the following result-

```
Created hard link successfully!!
```

# os.listdir() Method

## Description

given by path. The list is in arbitrary order. It does not include the special entries '. and '.. even if they are present in the directory. The method listdir() returns a list containing the names of the entries in the directory

path may be either of type str or of type bytes. If path is of type bytes, the filenames returned will also be of type bytes; in all other circumstances, they will be of type str.

#### Syntax

Following is the syntax for listdir() method-

```
os.listdir(path)
```

### **Parameters**

path - This is the directory, which needs to be explored.

## **Return Value**

path. This method returns a list containing the names of the entries in the directory given by

#### Example

The following example shows the usage of listdir() method.

```
dirs = os.listdir( path )
                                                                                                           path = "d:\\tmp\\"
                                                                                                                                                                import os, sys
                                                                                                                                                                                          #!/usr/bin/python3
                                                        # This would print
                                                                                                                                         # Open a file
                              for file in dirs:
print (file)
                                                          all the files and directories
```

When we run the above program, it produces the following result-

# os.lseek() Method

## **Description**

modified by how. The method Iseek() sets the current position of file descriptor fd to the given position pos,

#### Syntax

Following is the syntax for Iseek() method-

```
os.lseek(fd,
, sod
how)
```

### **Parameters**

- fd This is the file descriptor, which needs to be processed.
- **pos** This is the position in the file with respect to given parameter how. You give os.SEEK\_SET or 0 to set the position relative to the beginning of the file, os.SEEK\_CUR or 1 to set it relative to the current position; os.SEEK\_END or 2 to set it relative to the end of the file.
- beginning of the Moh os.SEEK\_END or 2 means end of the file This is the reference point with-in the file. ng of the file, os.SEEK\_CUR or 1 means the os.SEEK\_SET current position or 0 means and

# Defined **pos** constants

- os.SEEK\_SET 0
- os.SEEK\_CUR 1
- os.SEEK\_END 2

# Return Value

This method does not return any value.

#### Example

The following example shows the usage of Iseek() method

```
os.fsync(fd)
                                                                                                                 os.write(fd, b)
                                                                                                                                                                                                                                                                              #!/usr/bin/python3
                       # Now read this
                                                                    # Infact here you would not
                                                                                           # Now you can use fsync() method.
                                                                                                                                         b=line.encode()
                                                                                                                                                                                     # Write one string
                                                                                                                                                                                                           fd = os.open( "foo.txt",
                                                                                                                                                                                                                                   # Open a file
                                                                                                                                                                                                                                                          import os, sys

# os.lstat() Method

## Description

information about a file, but do not follow symbolic links. This is an alias for fstat() on platforms that do not support symbolic links, such as Windows. The method Istat() is very similar to fstat() and returns a stat\_result object containing the

Here is the structure returned by Istat method-

st\_dev: ID of device containing file

st\_ino: inode number

st\_mode: protection

st\_nlink: number of hard links

st\_uid: user ID of owner

st\_gid: group ID of owner

st\_rdev: device ID (if special file)

st\_size: total size, in bytes

st\_blksize: blocksize for filesystem I/O

st\_blocks: number of blocks allocated

st\_atime: time of last access

st\_mtime: time of last modification

st\_ctime: time of last status change

#### Syntax

Following is the syntax for Istat() method:

```
os.lstat(path)
```

### **Parameters**

path - This is the file for which information would be returned.

## **Return Value**

This method returns the information about a file.

#### Example

```
print
                                         print
                                                               # Now
                                                                                  print
                                                                                                                                            os.close( fd )
                                                                                                                                                                                                          path = "d:\\\python3\\\foo.txt"
                                                                                                       info = os.lstat(path)
                                                                                                                          # Now get the touple
                                                                                                                                                                   # Close opened file
                                                                                                                                                                                      fd = os.open( path,
                                                                                                                                                                                                                                 # Open a file
                                                                                                                                                                                                                                                     import os,
                                                                                                                                                                                                                                                                        #!/usr/bin/python3
                                                                                                                                                                                                                                                                                           The following example
                                                             get uid of the file
("GID of the file :%d"

# os.major() Method

## Description

the st\_dev or st\_rdev field from stat). The method major() extracts the device major number from a raw device number (usually

#### Syntax

Following is the syntax for major() method-

```
os.major(device)
```

### **Parameters**

**device** - This is a raw device number (usually the st\_dev or st\_rdev field from stat).

## **Return Value**

This method returns the device major number.

#### Example

The following example shows the usage of major() method

```
print ("Minor Device Number :", minor_dnum)
                                   print ("Major Device Number :", major_dnum)
                                                                               minor_dnum = os.minor(info.st_dev)
                                                                                                                   major_dnum = os.major(info.st_dev)
                                                                                                                                                                                                                                                                              path = "/var/www/html/foo.txt"
                                                                                                                                                                                                                                                                                                                                                           #!/usr/bin/python3
                                                                                                                                                             # Get major and minor device number
                                                                                                                                                                                                  info = os.lstat(path)
                                                                                                                                                                                                                                         # Now get
                                                                                                                                                                                                                                                                                                                    import os, sys
                                                                                                                                                                                                                                           the touple
```

When we run the above program, it produces the following result-

```
Minor Device Number
                 Major Device Number :

# os.makedev() Method

## **Description**

numbers. The method makedev() composes a raw device number from the major and minor device

#### Syntax

Following is the syntax for makedev() method-

```
os.makedev(major, minor)
```

### **Parameters**

- major This is Major device number.
- minor This is Minor device number.

## Return Value

This method returns the device number.

#### Example

The following example shows the usage of makedev() method.

```
print ("Device Number :", dev_num)
                                                                                                                                                                               print ("Minor Device Number :", minor_dnum)
                                                                                                                                                                                                                       print ("Major Device Number :", major_dnum)
                                                                                                                                                                                                                                                                                                                                                           # Get major and minor device number
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                path = "/var/www/html/foo.txt"
                                           dev_num = os.makedev(major_dnum, minor_dnum)
                                                                                            # Make a device number
                                                                                                                                                                                                                                                                   minor_dnum = os.minor(info.st_dev)
                                                                                                                                                                                                                                                                                                                                                                                                          info = os.lstat(path)

                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      #!/usr/bin/python3
                                                                                                                                                                                                                                                                                                                  major_dnum = os.major(info.st_dev)
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        import os, sys
```

When we run the above program, it produces the following result-

```
Device Number : 103
                             Minor Device Number
                                                      Major Device Number
                              103
```

# os.makedirs() Method

## Description

all intermediate-level directories needed to contain the leaf directory. The method makedirs() is recursive directory creation function. Like mkdir(), but makes

the current umask value is first masked out. The default mode is 0o777 (octal). On some systems, mode is ignored. Where it is used,

If exist\_ok is False (the default), an OSError is raised if the target directory already exists

#### Syntax

Following is the syntax for makedirs() method-

```
os.makedirs(path[,
mode])
```

## **Parameters**

- path This is the path, which needs to be created recursively.
- mode -This is the Mode of the directories to be given.

## Return Value

This method does not return any value

#### Example

The following example shows the usage of makedirs() method

```
path = "d:/tmp/home/monthly/daily"
                                                                                                                                                               #!/usr/bin/python3
print ("Path is created")
                              os.makedirs( path, 493 ) #decimal equivalent
                                                                                                                               import os,
                                                                                                 Path to be created
                                                                                                                                sys
                                 ٥f
                                0755 used on Windows
```

When we run the above program, it produces the following result-

```
Path
created
```

# os.minor() Method

## Description

The method minor() extracts the device minor number from a raw device number (usually the st\_dev or st\_rdev field from stat).

#### Syntax

Following is the syntax for minor() method-

```
os.minor(device)
```

### **Parameters**

**device** - This is a raw device number (usually the st\_dev or st\_rdev field from stat).

## **Return Value**

This method returns the device minor number.

#### Example

The following example shows the usage of minor() method.

```
print
                                                                                          minor_dnum = os.minor(info.st_dev)
                                                                                                                                                                                                                                                    path = "/var/www/html/foo.txt"
                               print ("Major Device Number :", major_dnum)
                                                                                                                                                          # Get major and minor device number
                                                                                                                                                                                           info =
                                                                                                                                                                                                                      # Now get the touple
                                                                                                                                                                                                                                                                                 import os, sys
                                                                                                                                                                                                                                                                                                                  #!/usr/bin/python3
                                                                                                                          major_dnum = os.major(info.st_dev)
 ("Minor Device Number
                                                                                                                                                                                         os.lstat(path)
 minor_dnum)
```

When we run the above program, it produces the following result-

```
Minor
              Major Device Number
Device Number
• •
 103
               0
```

# os.mkdir() Method

## Description

The method mkdir() create a directory named path with numeric mode mode. The default mode is 0777 (octal). On some systems, mode is ignored. Where it is used, the current umask value is first masked out.

#### Syntax

Following is the syntax for mkdir() method-

```
os.mkdir(path[, mode])
```

### **Parameters**

- path This is the path, which needs to be created.
- mode This is the mode of the directories to be given.

## **Return Value**

This method does not return any value.

#### Example

The following example shows the usage of mkdir() method.

```
path = "/tmp/home/monthly/daily/hourly"
                                                                                                 # Path to be created
                                                                                                                                                                   #!/usr/bin/python3
print "Path is created"
                               os.mkdir( path, 0755 );
                                                                                                                                  import os, sys
```

When we run the above program, it produces the following result-

```
Path is
created
```

# os.mkfifo() Method

## Description

The method **mkfifo()** create a FIFO named path with numeric mode. The default mode is 0666 (octal). The current umask value is first masked out.

FIFOs are pipes that can be accessed like regular files. FIFOs exist until they are deleted

#### Syntax

Following is the syntax for mkfifo() method-

```
os.mkfifo(path[, mode])
```

## **Parameters**

- path This is the path, which needs to be created.
- mode This is the mode of the named path to be given.

## **Return Value**

This method does not return any value.

#### Example

The following example shows the usage of mkfifo() method.

```
print ("Path is created")
                          os.mkfifo( path, 0644
                                                         path = "/tmp/hourly"
                                                                                         # Path to be created
                                                                                                                   import os, sys
                                                                                                                                                # !/usr/bin/python3
```

When we run the above program, it produces the following result-

```
Path is created
```

# os.mknod() Method

## Description

named filename. The method mknod() creates a filesystem node (file, device special file or named pipe)

#### Syntax

Following is the syntax for mknod() method-

```
os.mknod(filename[, mode=0600[, device=0]])
```

## **Parameters**

- filename This is the filesystem node to be created.
- **mode** The mode specifies both the permissions to use and the type of node to be created combined (bitwise OR) with one of the values stat.S\_IFREG, stat.S\_IFCHR, stat.S\_IFBLK, and stat.S\_IFIFO. They can be ORed base don requirement.
- device - This is the device special file created and its optional to provide

# **Return Value**

This method does not return any value. Available on Unix like systems.

#### Example

The following example shows the usage of mknod() method

```
mode = 0600|stat.S_IRUSR
                                # filesystem node specified with different modes
os.mknod(filename,
                                                                                             filename = '/tmp/tmpfile'
                                                                                                                                import stat
                                                                                                                                                              import os
                                                                                                                                                                                              !/usr/bin/python3
mode)
```

with a name tmpfile: Let us compile and run the above program, this will create a simple file in /tmp directory

```

```

# os.open() Method

## Description

The method **open()** opens the file file and set various flags according to flags and possibly its mode according to mode. The default mode is 0777 (octal), and the current umask value is first masked out.

#### Syntax

Following is the syntax for open() method:

```
os.open(file,
flags[,
mode]);
```

### **Parameters**

- **file** File name to be opened.
- **flags** The following constants are options for the flags. They can be combined using the bitwise OR operator |. Some of them are not available on all platforms.

  o os.O\_RDONLY: open for reading only
- 0 os.O\_WRONLY: open for writing only
- 0 os.O\_RDWR: open for reading and writing
- os.O\_NONBLOCK: do not block on open

```
    os.O_APPEND: append on each write
```

```
    os.O_CREAT: create file if it does not exist
```

```
    os.O_TRUNC: truncate size to 0
```

os.O\_EXCL: error if create and file exists

os.O\_SHLOCK: atomically obtain a shared lock

os.O\_EXLOCK: atomically obtain an exclusive lock

os.0\_DIRECT: eliminate or reduce cache effects

os.O\_FSYNC : synchronous writes

os.O\_NOFOLLOW: do not follow symlinks

**mode** - This work in similar way as it works for chmod() method

## **Return Value**

This method returns the file descriptor for the newly opened file

#### Example

The following example shows the usage of open() method.

```
print ("Closed the file successfully!!")
                                                                                                                                                                           # string needs to be converted byte object
                                  os.close(fd)
                                                                                                        os.write(fd, b)
                                                                                                                                           b=str.encode(line)
                                                                                                                                                                                                                                                 # Write one string
                                                                                                                                                                                                                                                                                    fd = os.open( "foo.txt", os.0_RDWR|os.0_CREAT )
                                                                                                                                                                                                                                                                                                                          # Open a file
                                                                                                                                                                                                                                                                                                                                                         import os, sys
                                                                                                                                                                                                                                                                                                                                                                                            #!/usr/bin/python3
                                                                                                                                                                                                                line="this is test"
                                                                   Close opened file
```

This would create given file foo.txt and then would write given content in that file and would produce the following result-

```
Closed the file successfully!!
```

# os.openpty() Method

## Description

The method **openpty()** opens a pseudo-terminal pair and returns descriptors(master, slave) for the pty & the tty respectively. മ pair of file

the pty module. The new file descriptors are non-inheritable. For a (slightly) more portable approach, use

#### Syntax

Following is the syntax for openpty() method-

```
os.openpty()
```

## **Parameters**

R

## **Return Value**

This method returns a pair of file descriptors i.e., master and slave.

#### Example

```
print( s)
                                                               # showing terminal name
                                                                                                             print (m)
                                                                                                                                                       # master for pty,
                                                                                                                                                                                                    # !/usr/bin/python3
                      print (m)
                                                                                       print (s)
                                                                                                                                    m,s = os.openpty()
                                                                                                                                                                               import os
                                                                                                                                                                                                                         The following example
                                             = os.ttyname(s)
                                                                                                                                                         slave for tty
                                                                                                                                                                                                                         shows the usage
                                                                                                                                                                                                                          of openpty() method.
```

When we run the above program, it produces the following result-

```
4
/dev/pty0
```

# os.pathconf() Method

## **Description**

The method pathconf() returns system configuration information relevant to a named file

#### Syntax

Following is the syntax for pathconf() method-

```
os.pathconf(path,
name)
```

## **Parameters**

- path This is the file path.
- operating system are given in the os.pathconf\_names dictionary. is the name of a defined system value; these names are specified in a number of standards (POSIX.1, Unix 95, Unix 98, and others). The names known to the host **name** - This specifies the configuration value to retrieve; it may be a string which

## Return Value

systems This method returns system configuration information of a file. Available on Unix like

#### Example

The following example shows the usage of pathconf() method.

```
print
print ("file
                                                                      print ("Maximum length of
                                                                                           no = os.pathconf('a2.py',
                                                                                                                                                                                        #!/usr/bin/python3
                                                                                                                   # Retrieve maximum length of a filename
                                                                                                                                                                import os,
                                                Retrieve file size
                      = os.pathconf('a2.py',
                                                                                                                                        ("%s"
                                                                                                                                                                 sys
                                                                                                                                        % os.pathconf_names)
   size in bits
                                                                        മ
                                                                                             'PC_NAME_MAX')
                         'PC_FILESIZEBITS')
 :%d" % no)
                                                                       filename :%d"
                                                                        % no)
```

When we run the above program, it produces the following result-

```

# os.pipe() Method

## **Description**

The method pipe() creates a pipe and returns reading and writing, respectively a pair of file descriptors (r, w) usable φ

#### Syntax

Following is the syntax for pipe() method-

```
os.pipe()
```

### **Parameters**

Z

## **Return Value**

This method returns a pair of file descriptors.

#### Example

The following example shows the usage of pipe() method

```
J
                                                                                                                                               if
                                                                                                                                                                       processid = os.fork()
                                                                                                                                                                                                                                                                                                                    print ("the parent will read the text written by child...")
                                                                                                                                                                                                                                                             # file descriptors r,
                                                                                                                                                                                                                                                                                                                                               print ("The child will write text to a pipe and ")
                                                                                                                                                                                                                                                                                                                                                                                                                                       #!/usr/bin/python3
                                                                                                                                                                                                                                                                                                                                                                                                          import os, sys

                                                                                child...
```

# os.popen() Method

## Description

object connected to the pipe, which can be read or written depending on whether mode is 'r' (default) or 'w'. The bufsize argument has the same meaning as in open() function. The method popen() opens a pipe to or from command. The return value is an open file

#### Syntax

Following is the syntax for popen() method-

```
os.popen(command[,
mode[,
bufsize]])
```

### **Parameters**

- command This is command used.
- mode This is the Mode can be 'r'(default) or 'w'.

system default(default behavior). specify the buffering value as an integer greater than 1, then buffering action will be performed with the indicated buffer size. If negative, the buffer size is the buffering value is 1, line buffering will be performed while accessing a file. If you bufsize - If the buffering value is set to 0, no buffering will take place. If the

## **Return Value**

This method returns an open file object connected to the pipe

#### Example

The following example shows the usage of popen() method

```
а
                                                                                        import os,
print b
                                                                                                            # !/usr/bin/python3
                                                                       using command mkdir
                                                       'mkdir nwdir'
              os.popen(a,'r',1)
                                                                                          sys
```

When we run the above program, it produces the following result-

```
open file
'mkdir nwdir',
 mode
٦_
 at
 0x81614d0
```

# os.read() Method

## **Description**

the bytes read. If the end of file referred to by fd has been reached, an empty string is returned. The method read() reads at most n bytes from file desciptor fd, return a string containing

open() or by popen() or fdopen(), or sys.stdin, use its read() or readline() methods. as returned by os.open() or pipe(). To read a "file object" returned by the built-in function Note: This function is intended for low-level I/O and must be applied to a file descriptor

#### Syntax

Following is the syntax for read() method-

```
os.read(fd,n)
```

### **Parameters**

- fd This is the file descriptor of the file.
- n These are n bytes from file descriptor fd.

# **Return Value**

This method returns a string containing the bytes read.

#### Example

The following example shows the usage of read() method

```
print ("Closed
                                                      # Close opened file
                                                                                                                                         # Reading text
                             os.close(fd)
                                                                                     print (ret.decode())
                                                                                                                                                                        fd = os.open("foo.txt",os.O_RDWR)
                                                                                                                                                                                                     # Open a file
                                                                                                                                                                                                                                import os, sys
                                                                                                               ret = os.read(fd,12)
                                                                                                                                                                                                                                                          !/usr/bin/python3
the file successfully!!")
```

Let us compile and run the above program, this will print the contents of file foo.txt-

```
This
Closed the file
                İS
successfully!!
```

# os.readlink() Method

### Description

The method **readlink()** returns a string representing the path to which the symbolic link points. It may return an absolute or relative pathname.

#### Syntax

Following is the syntax for readlink() method-

```
os.readlink(path)
```

### **Parameters**

path - This is the path or symblic link for which we are going to find source of the link.

## **Return Value**

This method return a string representing the path to which the symbolic link points.

#### Example

The following example shows the usage of readlink() method.

```
os.symlink(src, dst)
                                                                                                            SMC
print (path)
                                     # Now let us use readlink
                                                                                          dst = 'd://tmp//python2'
                                                                                                                               import
                                                                        This creates
                                                                                                                                                !/usr/bin/python3

                                     the link.
```

d:\tmp\python3 and later it will read the source of the symbolic link using readlink() call. This is an example on Windows platform and needs administrator privilege to run. Before running this program make sure you do not have d:\tmp\python2 already available. compile and run the above program. This will create ۵ symblic link V

```
d:\tmp\python2
```

# os.remove() Method

## Description

The method remove() removes the file path. If the path is a directory, OSError is raised.

#### Syntax

Following is the syntax for remove() method-

```
os.remove(path)
```

### **Parameters**

path - This is the path, which is to be removed.

## **Return Value**

This method does not return any value.

#### Example

The following example shows the usage of remove() method

```
os.chdir("d:\\tmp")
                   import os,
                                         !/usr/bin/python3
                   sys
```

```
print ("The
                                                                                                                                              #
                                                                                                                                                                                                           print ("The dir is: %s" %os.listdir(os.getcwd()))
                                                                                                        os.remove("test.java")
                                  listing directories after removing path
                                                                                                                                           removing
                                                                                                                                                                                                                                                listing directories

# os.rename() Method

## Description

directory(already present), OSError will be raised. The method **rename()** renames the file or directory src б dst. If dst S а <u>fi</u>e 윽

#### Syntax

Following is the syntax for rename() method-

```
os.rename(src,
dst)
```

### **Parameters**

- src This is the actual name of the file or directory.
- dst This is the new name of the file or directory.

## **Return Value**

This method does not return any value.

#### Example

The following example shows the usage of rename() method

```
# !/usr/bin/python3
import os, sys
```

```
print ("the dir is: %s" %os.listdir(os.getcwd()))
                                                 # listing directories after renaming "python3"
                                                                                                    print ("Successfully renamed.")
                                                                                                                                                    os.rename("python3", "python2")
                                                                                                                                                                                                   # renaming directory ''tutorialsdir"
                                                                                                                                                                                                                                                     print ("The dir is: %s"%os.listdir(os.getcwd()))
                                                                                                                                                                                                                                                                                                        # listing directories

# os.renames() Method

## **Description**

directories, that do not exist. functioning as os.rename(), but it also moves a file to a directory, or a whole tree of The method renames() is recursive directory or file renaming function. It does the same

#### Syntax

Following is the syntax for renames() method:

```
os.renames(old, new)
```

## **Parameters**

- old This is the actual name of the file or directory to be renamed.
- ${\bf new}$  This is the new name of the file or directory. It can even include a file to directory, or a whole tree of directories, that do not exist.

## Return Value

This method does not return any value.

#### Example

The following example shows the usage of renames() method.

```
print ("The dir is: %s" %os.listdir(os.getcwd()))
                                                                                                                                              # listing directories after renaming and moving "foo.txt"
                                                                                                                                                                                              print ("Successfully renamed.")
                                                                                                                                                                                                                                              os.renames("foo.txt","newdir/foonew.txt")
                                                                                                                                                                                                                                                                                             # renaming file "aa1.txt"
                                                                                                                                                                                                                                                                                                                                             print ("The dir is: %s"%os.listdir(os.getcwd()))

```

# os.rmdir() Method

## Description

empty, else OSError is raised. The method rmdir() removes the directory path. It works only when the directory is

#### Syntax

Following is the syntax for rmdir() method-

```
os.rmdir(path)
```

### **Parameters**

**path** - This is the path of the directory, which needs to be removed.

## **Return Value**

This method does not return any value.

#### Example

```
# listing directories
                                                                                                                                                                                                                       os.chdir("d:\\tmp")
                                                                                                                                                                    print ("the dir is: %s" %os.listdir(os.getcwd()))
                                                                                                                                                                                                                                                  import os, sys
                                                                                                                                                                                                                                                                                # !/usr/bin/python3
                                                                                                                                                                                                                                                                                                        The following example

# os.stat() Method

## **Description**

The method **stat()** performs a stat system call on the given path.

#### Syntax

Following is the syntax for stat() method-

```
os.stat(path)
```

## **Parameters**

path - This is the path, whose stat information is required.

## **Return Value**

Here is the list of members of stat structure-

- st\_mode: protection bits.
- st\_ino: inode number.
- st\_dev: device.
- st\_nlink: number of hard links.
- st\_uid: user id of owner.
- st\_gid: group id of owner.
- st\_size: size of file, in bytes.
- st\_atime: time of most recent access.
- st\_mtime: time of most recent content modification.
- st\_ctime: time of most recent metadata change.

#### Example

The following example shows the usage of stat() method.

```
# showing stat information of file "foo.txt"
                                                                                                                 # !/usr/bin/python3
statinfo = os.stat('foo.txt')
                                                                            import os, sys
```

```
print
(statinfo)
```

```
st_nlink=1,
                            os.stat_result(st_mode=33206,
st_ino=281474976797706,
               st_size=13,
                 st_atime=1455649253,
                            st_dev=1017554828,
```

# os.stat\_float\_times() Method

### **Description**

float objects. The method stat\_float\_times() determines whether stat\_result represents time stamps as

#### Syntax

Following is the syntax for stat\_float\_times() method-

```
os.stat_float_times([newvalue])
```

### **Parameters**

on stat returns ints. If newvalue is not mentioned, it returns the current settings. **newvalue** - If newvalue is True, future calls to stat() return floats, if it is False, future call

## **Return Value**

This method returns either True or False.

#### Example

The following example shows the usage of stat\_float\_times() method

```
print (statinfo)
                                                                                                                                                          # Stat information
                                                                                                                                                                                     import os,
                                                                                                                                                                                                                  #!/usr/bin/python3
print (statinfo)
                              statinfo = os.stat_float_times()
                                                                                                                         statinfo = os.stat('a2.py')
                                                                                                                                                                                     sys
```

When we run the above program, it produces the following result-

```
st_nlink=1,
os.stat_result(st_mode=33206,
            st_uid=0,
                          _ino=562949953508433,
             st_size=27,
             st_atime=1455597032,
                          st_dev=1017554828,
```

# os.statvfs() Method

## **Description**

The method statvfs() perform a statvfs system call on the given path.

#### Syntax

Following is the syntax for statvfs() method-

```
os.statvfs(path)
```

## **Parameters**

path - This is the path, whose statvfs information is required.

## **Return Value**

Here is the list of members of statvfs structure-

- f\_bsize: preferred file system block size.
- f\_frsize: fundamental file system block size.
- f\_blocks: total number of blocks in the filesystem.
- f\_bfree: total number of free blocks.
- f\_bavail: free blocks available to non-super user.
- f\_files: total number of file nodes.
- f\_ffree: total number of free file nodes.
- f\_favail: free nodes available to non-super user.
- f\_flag: system dependent.
- f\_namemax: maximum file name length.

#### Example

systems-The following example shows the usage 으 statvfs() method. Availabe on Unix like

```
import os,
                                                # !/usr/bin/python3
 stinfo =
               showing statvfs
os.statvfs('a1.py')
                                sys
                information
                ٩
                file
                "a1.py"
```

```
print
(stinfo)
```

```
posix.statvfs_result(f_bsize=4096, f_frsize=4096, f_blocks=1909350L,
f_bfree=1491513L,
                                         f_bavail=1394521L,
f_namemax=255)
                                         f_files=971520L, f_ffree=883302L, f_fvail=883302L,
                                         f_flag=0,
```

# os.symlink() Method

## **Description**

The method symlink() creates a symbolic link dst pointing to src.

#### **Syntax**

Following is the syntax for symlink() method-

```
os.symlink(src, dst)
```

### **Parameters**

- **src** This is the source
- dest This is the destination, which did not exist previously.

## Return Value

This method does not return any value.

#### Example

The following example shows the usage of symlink() method-

```
print
                                                        # This creates a symbolic link on python in tmp directory
                                                                                  dst = '/tmp/python'
                                                                                                               src = '/usr/bin/python3'
                          os.symlink(src, dst)
                                                                                                                                             import os
                                                                                                                                                                         #!/usr/bin/python3
  "symlink
created"
```

Let us compile and run the above program, this will create a symbolic link in /tmp directory which will be as follows-  $\,$ 

1rwxrwxrwx. 1 root root 15 Apr 30 03:00 python -> /usr/bin/python3

# os.tcgetpgrp() Method

## Description

The method tcgetpgrp() returns the process group associated with the terminal given by fd (an open file descriptor as returned by os.open())

#### Syntax

Following is the syntax for tcgetpgrp() method-

```
os.tcgetpgrp(fd)
```

### **Parameters**

fd - This is the file descriptor.

## **Return Value**

This method returns the process group.

#### Example

The following example shows the usage of tcgetpgrp() method-

```
print
print ("Closed the file successfully!!")

# os.tcsetpgrp() Method

## **Description**

The method tcsetpgrp() sets the process group associated with the terminal given by fd (an open file descriptor as returned by os.open()) to pg.

### Syntax

Following is the syntax for tcsetpgrp() method-

```
os.tcsetpgrp(fd,
pg)
```

## **Parameters**

- **fd** This is the file descriptor.
- pg This set the process group to pg.

## **Return Value**

This method does not return any value

### Example

The following example shows the usage of tcsetpgrp() method.

```
print
print (f)
                                                                                                                                      fd =
                                                                                                                                                                                                    print ("Current working dir
                                                                                                                                                                                                                                                import os,
                                                                                          ┪
                                                                                                                                                                                                                                                                       # !/usr/bin/python3

 file
successfully!!
                                                                              :/tmp
```

# os.tempnam() Method

## Description

The method tempnam() returns a unique path name that is reasonable for creating a temporary file.

#### Syntax

Following is the syntax for tempnam() method-

```
os.tempnam(dir,
 prefix)
```

## **Parameters**

- dir This is the dir where the temporary filename will be created.
- prefix This is the prefix of the generated temporary filename.

## **Return Value**

This method returns a unique path.

### Example

The following example shows the usage of tempnam() method.

```
# prefix is tuts1 of the generated file
tmpfn = os.tempnam('/tmp/tutorialsdir,'tuts1')
                                                                        import os,
                                                                                                            !/usr/bin/python3
                                                                          sys
```

```
print
print tmpfn
          "This
          is
          the
          unique
         path:"
```

When we run the above program, it produces the following result-

```
tmp/tutorialsdir/tuts1IbAco8/
                                     the unique path:
```

# os.tmpfile() Method

## **Description**

there are no file descriptors. The method tmpfile() returns a new temporary file object opened in update mode (w+b). The file has no directory entries associated with it and will be deleted automatically once

#### Syntax

Following is the syntax for tmpfile() method-

```
os.tmpfile
```

## **Parameters**

Ν

## **Return Value**

This method returns a new temporary file object.

### Example

The following example shows the usage of tmpfile() method.

```
print
                                                                                                                                                                                                       import os
                                                                                                                                                                                                                                 # !/usr/bin/python3
                                                         tmpfile.seek(0)
                                                                                     tmpfile.write('Temporary newfile is here....')
                                                                                                                 tmpfile = os.tmpfile()
                                                                                                                                              deleted automatically
                                                                                                                                                                         The file has no directory entries associated with it and will be
tmpfile.read()

# os.ttyname() Method

## Description

The method **ttyname()** returns a string, which specifies the terminal device associated with fd. If fd is not associated with a terminal device, an exception is raised.

### Syntax

Following is the syntax for ttyname() method-

```
os.ttyname(fd)
```

## **Parameters**

fd - This is the file descriptor.

## **Return Value**

Systems. This method returns a string which specifies the terminal device. Available on Unix like

### Example

The following example shows the usage of ttyname() method

```
print
print ("Closed the file successfully!!")
                                                                                   print ("done!!")
                                                                                                                                          print ("the terminal device associated is: ")
                                                                                                                                                                                                                                fd =
                                                                                                                                                                                                                                                                                                                   print ("Current working dir :%s" %os.getcwd())
                           os.close(fd)
                                                                                                                                                                                                                                                                                                                                                                                                       import os,
                                                                                                                                                                                                                                                          Changing dir to
                                                                                                                                                                                                                                                                                                                                                Showing current directory
                                                                                                                                                                                                                                                                                                                                                                                                                                     !/usr/bin/python33
                                                                                                                                                                    os.ttyname(fd)
                                                                                                                                                                                                                               os.open("/dev/tty",os.O_RDONLY)
                                                                                                                                                                                                                                                                                                                                                                                                          sys
                                                                                                                                                                                                                                                              /dev/tty
```

```

# os.unlink() Method

## Description

Unix name. is raised. This function is identical to the remove() mehod; the unlink name is its traditional The method unlink() removes (deletes) the file path. If the path is a directory, OSError

#### Syntax

Following is the syntax for unlink() method-

```
os.unlink(path)
```

## **Parameters**

path - This is the path, which is to be removed.

## **Return Value**

This method does not return any value

### Example

The following example shows the usage of unlink() method.

```
print ("The dir after removal of path : %s"
                                          # listing directories after removing path
                                                                                                                               print ("The dir is: %s" %os.listdir(os.getcwd()))
                                                                                                                                                                                                                 os.chdir("d:\\tmp")
                                                                                        os.unlink("foo.txt")
                                                                                                                                                                         # listing directories
                                                                                                                                                                                                                                                           import os, sys

# os.utime() Method

## Description

The method utime() sets the access and modified times of the file specified by path.

### Syntax

Following is the syntax for utime() method-

```
os.utime(path,
times)
```

## **Parameters**

- path This is the path of the file.
- of row in the form of (atime, mtime) i.e (accesstime, modifiedtime). access and modified times are set to the current time. The parameter times consists times This is the file access and modified time. If times is none, then the file

## **Return Value**

This method does not return any value.

### Example

The following example shows the usage of utime() method.

```
print

## os.walk() Method

## Description

top-down or bottom-up. The method walk() generates the file names in a directory tree by walking the tree either

### Syntax

Following is the syntax for the walk() method-

```
os.walk(top[,
topdown=True[,
onerror=None[,
followlinks=False]]])
```

## **Parameters**

- filenames) top - Each directory rooted at directory, yields 3-tuples, i.e., (dirpath, dirnames,
- **topdown** If optional argument topdown is True or not specified, directories are scanned from top-down. If topdown is set to False, directories are scanned from bottom-up. to False, directories are
- abort the walk. onerror - This can show error to continue with the walk, or raise the exception to
- followlinks This visits directories pointed to by symlinks, if set to true.

## Return Value

This method does not return any value.

### Example

The following example shows the usage of walk() method.

```
import os
                     !/usr/bin/python3
```

```
os.chdir("d:\\tmp")
                                                                                                               for root, dirs, files
                                                                                     for
                              for
                              name in dirs:
                                                                                     name in files:
                                                       print(os.path.join(root, name))
print(os.path.join(root, name))
                                                                                                                in os.walk(".",
                                                                                                                topdown=False):

```
.\python2\testdir\Readme_files\ParallelPortViever.gif
                                                                  .\python2\testdir\Readme_files\Lpt_Port_Config.gif
```

.\python2\testdir\Readme\_files\Thumbs.db

\python2\testdir\Readme\_files\softcollection.css

- .\python2\testdir\Readme\_files\Yellov\_Ball.gif
- \python2\testdir\Readme.htm
- \python2\testdir\Readme\_files
- \python2\testdir
- \Applicationdocs.docx
- \book.zip
- .\foo.txt
- \java.ppt
- \python2

If you will change the value of topdown to True, then it will give you the following result-

```
.\Applicationdocs.docx
```

- \book.zip
- \foo.txt \java.ppt
- .\python2
- \python2\testdir
- \python2\testdir\Readme.htm
- .\python2\testdir\Readme\_files
- .\python2\testdir\Readme\_files\Lpt\_Port\_Config.gif
- .\python2\testdir\Readme\_files\ParallelPortViever.gif
- .\python2\testdir\Readme\_files\softcollection.css
- .\python2\testdir\Readme\_files\Thumbs.db

```
.\python2\testdir\Readme_files\Yellov_Ball.gif
```

# os.write() Method

## Description

The method **write()** writes the string str to file descriptor fd. It returns the number of bytes actually written.

#### Syntax

Following is the syntax for write() method-

```
os.write(fd,
str)
```

## **Parameters**

- **fd** This is the file descriptor.
- str This is the string to be written.

## **Return Value**

This method returns the number of bytes actually written.

### Example

The following example shows the usage of the write() method-

```
print ("Closed the
                                                                                                          print ("the number of bytes written: ", ret)
                                       os.close(fd)
                                                                          # Close opened file
                                                                                                                                                                                                                                                                                                                                  # Write one string
                                                                                                                                                                                                                                                                                                                                                                                                            # Open a file
                                                                                                                                                                                                                                                                                                                                                                                                                                               import os,
                                                                                                                                                                                    ret=os.write(fd, b)
                                                                                                                                                                                                                        b=str.encode(line)
                                                                                                                                                                                                                                                                                                  line="this is test"
                                                                                                                                                                                                                                                                                                                                                                       fd = os.open( "f1.txt", os.0_RDWR|os.0_CREAT )
                                                                                                                                                                                                                                                           string needs to be converted byte object
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    !/usr/bin/python3
                                                                                                                                              consists of number of bytes written to f1.txt
                                                                                                                                                                                                                                                                                                                                                                                                                                               sys
file successfully!!")
```

the number of bytes written: 12

Closed the file successfully!!

# 18. Python 3 — Exceptions Handling

Python provides two very important features to handle any unexpected error in your Python programs and to add debugging capabilities in them-

- Exception Handling.
- Assertions.

# Standard Exceptions

Here is a list of Standard Exceptions available in Python.

Exception  Exception  StopIteration	Base class for all exceptions  Raised when the next() method of an iterator does not point to any object.
SystemExit	Raised by the sys.exit() function.
StandardError	Base class for all built-in exceptions except StopIteration and SystemExit.
ArithmeticError	Base class for all errors that occur for numeric calculation.
OverflowError	Raised when a calculation exceeds maximum limit for a numeric type.
FloatingPointError	Raised when a floating point calculation fails.
ZeroDivisonError	Raised when division or modulo by zero takes place for all numeric types.
AssertionError	Raised in case of failure of the Assert statement.
AttributeError	Raised in case of failure of attribute reference or assignment.

SystemExit Raised functio exit.	SystemError Raised this en	IndentationError Raised	SyntaxError Raised	OSError Raised	IOError Raised statem does n	EnvironmentError Base class f	UnboundLocalError Raised metho	NameError Raised when namespace.	KeyError	IndexError Raised	LookupError Base c	KeyboardInterrupt Raised pressir	ImportError Raised	EOFError Raised input()
Raised when Python interpreter is quit by using the sys.exit() function. If not handled in the code, causes the interpreter to exit.	Raised when the interpreter finds an internal problem, but when this error is encountered the Python interpreter does not exit.	Raised when indentation is not specified properly.	Raised when there is an error in Python syntax.	Raised for operating system-related errors.	Raised when an input/ output operation fails, such as the print statement or the open() function when trying to open a file that does not exist.	class for all exceptions that occur outside the Python onment.	Raised when trying to access a local variable in a function or method but no value has been assigned to it.	when an identifier is not found in the local or global pace.	Raised when the specified key is not found in the dictionary.	Raised when an index is not found in a sequence.	Base class for all lookup errors.	Raised when the user interrupts program execution, usually by pressing Ctrl+c.	Raised when an import statement fails.	Raised when there is no input from either the raw_input() or input() function and the end of file is reached.

Raised when an abstract method that needs to be implemented in an inherited class is not actually implemented.	NotImplementedError
Raised when a generated error does not fall into any category.	RuntimeError
Raised when the built-in function for a data type has the valid type of arguments, but the arguments have invalid values specified.	ValueError
Raised when an operation or function is attempted that is invalid for the specified data type.	TypeError

# Assertions in Python

your testing of the program. An assertion is a sanity-check that you can turn on or turn off when you are done with

- result comes up false, an exception is raised. be more accurate, a raise-if-not statement). An expression is tested, and if the The easiest way to think of an assertion is to liken it to a raise-if statement (or to
- introduced in version 1.5. Assertions are carried out by the assert statement, the newest keyword to Python,
- Programmers often place assertions at the start of a function to check for valid input, and after a function call to check for valid output.

# The assert Statement

When it encounters an assert statement, Python evaluates the accompanying expression, which is hopefully true. If the expression is false, Python raises anAssertionError exception. hopefully false,

The syntax for assert is -

assert Expression[, Arguments]

program and produce a traceback. exception, using the try-except statement. If they are not handled, they will terminate the AssertionError. AssertionError exceptions assertion fails, Python uses ArgumentExpression as can be caught and handled like any other the argument for

### Example

temperature Fahrenheit. Since 0° K is as cold as it gets, the function bails out if it sees a negative Here is a function that converts a given temperature from degrees Kelvin to degrees

```
print
                                                                   print
print (KelvinToFahrenheit(-5))
                                                                                                                                                                                                                                                     #!/usr/bin/python3
                                                                                                                                                                                                                  KelvinToFahrenheit(Temperature):
                                                                                                                                                                           assert (Temperature >= 0),"Colder
                                                                                                                                          return ((Temperature-273)*1.8)+32
                                                                     (KelvinToFahrenheit(273))
                                 (int(KelvinToFahrenheit(505.78)))
                                                                                                                                                                            than absolute zero!"
```

When the above code is executed, it produces the following result-

```
451
                                                                                                                                                                                                                          32.0
                           assert (Temperature >= 0), "Colder than absolute
                                                                                                                         File "test.py",
AssertionError: Colder than absolute zero!
                                                                                           print KelvinToFahrenheit(-5)
                                                                                                                                                          Traceback (most recent call last):
                                                       "test.py", line 4,
                                                                                                                            line 9,
                                                             in KelvinToFahrenheit
                                                                                                                             ı.
                            zero!"
```

# What is Exception?

a situation that it cannot cope with, it raises an exception. An exception is a Python object the normal flow of the program's instructions. In general, when a Python script encounters that represents an error. An exception is an event, which occurs during the execution of a program that disrupts

otherwise it terminates and quits When a Python script raises an exception, it must either handle the exception immediately

# Handling an Exception

as possible. an except: statement, followed by a block of code which handles the problem as elegantly program by If you have some suspicious code that may raise placing the suspicious that may raise an exception, you can defend your code in a **try:** block. After the try: block, include

### Syntax

Here is simple syntax of try....except...else blocks-

```
You do your operations here
```

```
except
                                                                                                                                                                          except ExceptionII:
                                                                                                                                If there is ExceptionII, then execute this block.
there is no exception then execute this block.
                                                                                                                                                                                                                                                                   ExceptionI:
                                                                                                                                                                                                                       is ExceptionI, then execute this block.
```

Here are few important points about the above-mentioned syntax-

- the try block contains statements that may throw different types of exceptions. A single try statement can have multiple except statements. This is useful when
- You can also provide a generic except clause, which handles any exception.
- After the except clause(s), you can include an else-clause. The code in the elseblock executes if the code in the try: block does not raise an exception.
- The else-block is protection. ۵ good place for code that does not need the try: block's

### Example

is no problem at all. This example opens a file, writes content in the file and comes out gracefully because there

```
#!/usr/bin/python3
                                                                                                                                                     except IOError:
                                                                                                            print ("Error: can\'t find file or read data")
                                     print ("Written content in the
                                                                                                                                                                                         fh.write("This is my test file for exception handling!!")
                                                                                                                                                                                                                                fh = open("testfile", "w")
fh.close()
                                        file
                                     successfully")
```

This produces the following result-

```
Written content
 'n.
the
 file
successfully
```

### Example

an exception-This example tries to open a file where you do not have the write permission, so it raises

```
except IOError:
                                                                                                                                                                                                                                                                           #!/usr/bin/python3
                                                                            print ("Error: can\'t find file or read data")
                                                                                                                                                         fh.write("This is my test file for exception handling!!")
                                                                                                                                                                                             fh = open("testfile", "r")
print ("Written content in the
 file
   successfully")
```

This produces the following result-

```
Error:
can't
find
file
ဝှ
read data
```

# The except Clause with No Exceptions

You can also use the except statement with no exceptions defined as follows

```
except:
                                                                                                                                                                                                         NoA
If there is no exception then execute this block.
                                                                                                       If there is any exception, then execute this block.
                                                                                                                                                                                                            do
                                                                                                                                                                                                         your operations
                                                                                                                                                                                                            here
```

it catches all exceptions but does not make the programmer identify the root cause of the of try-except statement is not considered a good programming practice though, because problem that may occur. This kind of a **try-except** statement catches all the exceptions that occur. Using this kind

# The except Clause with Multiple Exceptions

You can also use the same except statement to handle multiple exceptions as follows-

```
except(Exception1[, Exception2[,...ExceptionN]]]):
                                        If there is
then execute this block.
                                                                                                                                                           You do your operations here
                                    any exception from
                                    the given exception list,
```

```
else:
If there
1s
no
exception then execute
this block.
```

# The try-finally Clause

any code that must execute, whether the try-block raised an exception or not. of the try-finally statement is this-You can use a finally: block along with a try: block. The finally: block is a place The syntax to put

```
finally:
                                                                                                                 Due to any exception, this may be skipped.
                                        This would always be executed.
                                                                                                                                                                                         You do your operations here;
```

use *else* clause as well along with a finally clause.

### Example

```
#!/usr/bin/python3
                             print ("Error:
                                                                                                     fh.write("This is my test file for exception handling!!")
                                                                                                                                     fh = open("testfile", "w")
fh.close()
                                  can\'t
                                find file or read data")
```

If you do not have following resultpermission to open the file in writing mode, then this will produce the

```
Error:
can't find
file
ဝှ
read
 data
```

Same example can be written more cleanly as follows-

```
#!/usr/bin/python3
                     try:
                                      fh =
fh.write("This
                                      open("testfile", "w")
  is
 my test
   file
for exception handling!!")
```

```
except IOError:
print ("Error: can\'t find file or read data")
                                                                                                                                                   finally:
                                                                        fh.close()
                                                                                                           print ("Going to close the file")
```

the finally block. After all the statements in the finally block are executed, the exception of the try-except statement. is raised again and is handled in the except statements if present in the next higher layer When an exception is thrown in the try block, the execution immediately passes

# Argument of an Exception

An exception can have an argument, which is a value that gives additional information about the problem. The contents of the argument vary by exception. You capture an exception's argument by supplying a variable in the except clause as followsthe argument vary by exception. You capture an

```
except ExceptionType as Argument:
You can print value of Argument here...
                                                                                                                                                                               You do your operations here
```

of the exception in the except statement. If you are trapping multiple exceptions, you can have a variable follow the tuple of the exception. If you write the code to handle a single exception, you can have a variable follow the name

exception. The variable can receive a single value or multiple values in the form of a tuple. This variable receives the value of the exception mostly containing the cause of the This tuple usually contains the error string, the error number, and an error location.

### Example

Following is an example for a single exception-

```
print("The argument does not contain numbers\n",Argument)
                                                                                                                                                                                                                                                                                                                                                                                                          #!/usr/bin/python3
                                                                                                                                     except ValueError as Argument:
                                                                                                                                                                                   returnint(var)
                                                                                                                                                                                                                                                                      def temp_convert(var):
                                                                                                                                                                                                                                                                                                                     # Define a function here.
Call above function here.
```

```
temp_convert("xyz")
```

This produces the following result-

```
invalid literal for int() with base 10:
                                            The argument does not contain numbers
   'xyz'
```

# Raising an Exception

for the raise statement is as follows-You can raise exceptions in several ways by using the raise statement. The general syntax

#### Syntax

```
[Exception
C
args
traceback]]]
```

Here, argument is None. value for the exception argument. The argument is optional; if not supplied, the exception Exception is the type of exception (for example, NameError) and argument is

The final argument, traceback, is also optional (and rarely used in practice), and if present, is the traceback object used for the exception.

### Example

An exception can be a string, a class or an object. Most of the exceptions that the Python core raises are classes, with an argument that is an instance of the class. Defining new exceptions is quite easy and can be done as follows-

```
def functionName( level ):
return level
                                                                                                                                                if level <1:
                                                                       #
                                                                       The code below to this would not be executed
                                     if we raise the exception
                                                                                                        Exception(level)
```

exception, we must write the except clause as followsthrown either as a Note: In order to catch an exception, an "except" clause must refer to the same exception class object or a simple string. For example, to capture the above

```
except Exception as e:
Exception handling
                                               Business Logic here.

The following example illustrates the use of raising an exception-

```
l=functionName(-10)
print ("level=",1)
except Exception as e:
                                                                                                try:
                                                                                                                                                                                                                                                                                     #!/usr/bin/python3
print ("error in level argument",e.args[0])
                                                                                                                                                                                                                                       if level <1:
                                                                                                                                                                                                                                                        functionName( level ):
                                                                                                                                               return level
                                                                                                                                                                 # if we raise the exception
                                                                                                                                                                                          # The code below to this would not be executed
                                                                                                                                                                                                                raise Exception(level)
```

This will produce the following result-

```
error in level argument
  -10
```

# **User-Defined Exceptions**

Python also allows you to create your own exceptions by deriving classes from the standard built-in exceptions.

Here is an example related to *RuntimeError*. Here, a class is created that is subclassed from *RuntimeError*. This is useful when you need to display more specific information when an exception is caught.

In the try block, the user-defined exception is raised and caught in the except block. The variable  ${f e}$  is used to create an instance of the class Networkerror.

```
class Networkerror(RuntimeError):
                    def
self.args
                   _init_
                 (self, arg):
= arg
```

So once you have defined the above class, you can raise the exception as follows-

```
except Networkerror, e:
print e.args
                                                                      raise Networkerror("Bad hostname")
```

# Python 3 **Advanced Tutorial**

# Python 3 — Object Oriented

an expert in using Python's object-oriented programming support. creating and using classes and objects are downright easy. This chapter helps you become Python has been an object-oriented language since the time it existed. Due

may want to consult an introductory course on it or at least a tutorial of some sort so that If you do not have any previous experience with object-oriented (OO) programming, you a grasp of the basic concepts.

However, here is a small introduction of Object-Oriented Programming (OOP) to help you.

# Overview of OOP Terminology

- variables and instance variables) and methods, accessed via dot notation. Class: A user-defined prototype for an object that defines any object of the class. The attributes are a set of attributes that data members (class
- Class variable: A variable that is shared by all instances of a class. Class variables not used as frequently as instance variables are defined within a class but outside any of the class's methods. Class variables
- a class and its objects. Data member: A class variable or instance variable that holds data associated with
- Function overloading: The assignment of more than one behavior to a particular function. The operation performed varies by the types of objects or arguments
- Instance variable: A variable that is defined inside a method and belongs only to current instance of a class
- **Inheritance:** The transfer of the characteristics of a class to other classes that are
- class Circle, for example, is an instance of the class Circle Instance: An individual object of a certain class. An object obj that belongs
- Instantiation: The creation of an instance of a class.
- Method: A special kind of function that is defined in a class definition.
- comprises **Object:** A unique instance of a data structure that is defined by its class. An object methods. both data members (class variables and instance variables) and
- operator. Operator overloading: The assignment of more than one function to a particular

## **Creating Classes**

follows the keyword class followed by a colon as follows-The class statement creates a new class definition. The name of the class immediately

```
class ClassName:
class_suite
                                      'Optional class documentation string
```

- viaClassName. The class has \_doc\_ а documentation string, which can be accessed
- data attributes and functions. The class\_suite consists of all the component statements defining class members,

### Example

Following is an example of a simple Python class-

```
class Employee:
                                                                                                                                                                    def
                    def displayEmployee(self):
                                                                         def displayCount(self):
                                                                                                                                                                                                      empCount = 0
                                                                                                                                                                                                                         'Common base
                                                      print "Total Employee %d"
  print ("Name :
                                                                                                                                self.salary
                                                                                                                                                  self.name =
                                                                                                             Employee.empCount +=
                                                                                                                                                                  _init__(self, name,
                                                                                                                                                                                                                         class
                                                                                                                                                  name
                                                                                                                               = salary
ζ=
                                                                                                                                                                                                                         for
self.name,
                                                                                                                                                                                                                        all employees'
                                                                                                              \vdash
                                                                                                                                                                  salary):
                                                         %
                                                         Employee.empCount
ζ=
  Salary:
ς=
  self.salary)
```

- The variable empCount is a class variable whose value is shared among all the instances of **a** in this class. This can be accessed as Employee.empCount from inside the class or outside the class.
- The first method  $\underline{\quad}$  is a special method, which is called class constructor or initialization method that Python calls when you create a new instance of this
- You declare other class methods like normal functions with the exception that the first argument to each method is *self*. Python adds the *self* argument to the list for you; you do not need to include it when you call the methods.

# **Creating Instance Objects**

To create instances of a class, you call the class using class name arguments its \_\_init\_\_ method accepts. and pass in whatever

```
This
                                                                                                         emp1 = Employee("Zara", 2000)
                                                                                                                                                 This would create first object of Employee class
                                   would create second object
Employee("Manni", 5000)
                                   of Employee class
```

# **Accessing Attributes**

You access the object's attributes using the dot operator with object. Class variable would be accessed using class name as follows-

```
print ("Total Employee %d"
                                      emp2.displayEmployee()
                                                                        emp1.displayEmployee()
% Employee.empCount)
```

Now, putting all the concepts together-

```
#This would create second object of Employee class"
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            #!/usr/bin/python3
                            emp1 = Employee("Zara", 2000)
                                                        #This would create first object of Employee class"
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                 class Employee:
                                                                                                                                                                                                                                                                                                                                                              def
                                                                                                               def displayEmployee(self):
                                                                                                                                                                                                        def displayCount(self):

                                                                                                                                                                                                                                                                                                                                                         _init__(self, name, salary):
                                                                                    self.name,
                                                                                                                                                                            % Employee.empCount)
                                                                              . =
                                                                                     Salary:
                                                                               _=
                                                                                     self.salary)
```

```
print ("Total Employee
                       emp2.displayEmployee()
                                               emp1.displayEmployee()
                                                                     Employee("Manni",
  %d"
 %
Employee.empCount)
```

When the above code is executed, it produces the following result-

```
Total Employee 2
                 Manni ,Salary:
                                     Zara ,Salary:
                                      2000
                    5000
```

You can add, remove, or modify attributes of classes and objects at any time

```
del emp1.salary
                                                             emp1.salary = 7000
                                'xyz'
# Delete 'age' attribute.
                                # Modify 'age' attribute.
                                                               # Add an 'salary' attribute.
```

functions-Instead of using the normal statements to access attributes, you can use the following

- The getattr(obj, name[, default]): to access the attribute of object.
- The hasattr(obj,name): to check if an attribute exists or not
- it would be created. The **setattr(obj,name,value)**: to set an attribute. If attribute does not exist, then
- The delattr(obj, name): to delete an attribute.

```
setattr(emp1,
                                  getattr(emp1,
delattr(emp1,
                                                   hasattr(emp1,
                'salary',
'salary')
                                  'salary')
                                                  'salary')
                  7000) # Set attribute
                                 # Returns value of
# Delete attribute
                                                   #
                                                    Returns
                                                   true if
                                                    'salary'
               'age'
                                  'salary' attribute
'age'
                  at
                                                    attribute
                   \infty
                                                    exists
```

# **Built-In Class Attributes**

dot operator like any other attribute Every Python class keeps the following built-in attributes and they can be accessed using

- \_dict\_ Dictionary containing the class's namespace
- <u>\_ooc</u> : Class documentation string or none, if undefined
- \_\_name\_\_: Class name.
- \_module \_main\_\_ \_" in interactive mode. \_: Module name in which the class S. defined. This attribute S.

their occurrence in the base class list. \_bases \_: A possibly empty tuple containing the base classes, in the order of

For the above class let us try to access all these attributes

```
print ("Employee.__dict__:", Employee.__dict__ )
                                                            print
                                                                                       print ("Employee.__name__:", Employee.__name__)
                                                                                                                       print ("Employee._
                                                                                                                                                      emp2 =
                                                                                                                                                                                   emp1 =
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       class Employee:
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  #!/usr/bin/python3
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    def

                                                                                                         _del_
                                                                                                                                                               _init( self, x=0, y=0):
                                                                                                        _(self):
                                                                      "destroyed")
                                                                                        _class
```

```
del
del pt3
                del pt2
                                                print (id(pt1), id(pt2), id(pt3) # prints
                                pt1
                                                  the ids
                                                 οf
                                                  the
                                                obejcts)
```

When the above code is executed, it produces the following result-

```
Point destroyed
                                          3083401324 3083401324 3083401324
```

them in your main program file using import statement. Note: Ideally, you should define your classes in a separate file, then you should import

is no other executable code in it. In the above example, assuming definition of a Point class is contained in point.py and there

```
p1=point.Point()
                          import point
                                                  #!/usr/bin/python3
```

# Class Inheritance

class by listing the parent class in parentheses after the new class name. Instead of starting from a scratch, you can create a class by deriving it from a pre-existing

as if they were defined in the child class. A child class can also override data members and methods from the parent. The child class inherits the attributes of its parent class, and you can use those attributes

#### Syntax

to inherit from is given after the class name Derived classes are declared much like their parent class; however, a list of base classes

```
class SubClassName
class_suite
                                'Optional class
                                documentation string
                                                                 (ParentClass1[, ParentClass2,
```

### Example

```
#!/usr/bin/python3
                                              class Parent:
                       parentAttr = 100
 _init
_(self):
                                             define parent class
```

```
c.setAttr(200)
                                                c.parentMethod()
                                                                        c.childMethod()
c.getAttr()
                                                                                                                                                                                                                                                                   class Child(Parent): # define child class
                                                                                                = Child()
                                                                                                                                                                                                                                            def
                                                                                                                                                                                                                                                                                                                                          def

                                                                                                                                                                                                                                                                                                                                       getAttr(self):
                                                                                                                                                                                                                                             _init_
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                           ("Calling parent
                                                                                                                                                                                                                                           _(self):
  #
                           #
                                                 #
                                                                        #
                                                                                                #
again
                     again
                                                  calls
                                                                         child calls its method
                                                                                                instance of child
                        call parent's method
                                                 parent's method
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            constructor")
call parent's method
```

When the above code is executed, it produces the following result-

```
Calling
Parent attribute : 200
                        Calling parent method
                                                                        Calling child constructor
                                                   child method
```

In similar way, you can drive മ class from multiple parent classes as follows-

```
:
                                                       class
           class C(A, B):
                                  class
                                  ₽.
                                                        ₽
            #
                                                       define your class A
            subclass
                                 define your
            숙
           ⊳
                                  calss B
           and B
```

You can use issubclass() or isinstance() functions to check a relationship of two classes and instances.

- subclass **sub** is indeed a subclass of the superclass **sup**. The issubclass(sub, **sup)** boolean function returns True, ≕; the given
- class Class or is an instance of a subclass of Class. The isinstance(obj, Class) boolean function returns True, if obj is an instance of

# Overriding Methods

methods is that you may want special or different functionality in your subclass. You can always override your parent class methods. One reason for overriding parent's

### Example

```
c.myMethod()
                                                                                                                                                                                                                                                                                                           #!/usr/bin/python3
                                                                                                                                        class Child(Parent): # define child class
                                                                                                                                                                                                                                                     class Parent:
                            = Child()
                                                                                                                                                                                                                          def myMethod(self):
                                                                                                             def myMethod(self):
                                                                               print ('Calling child method')
                                                                                                                                                                                            print ('Calling parent method')
  #
                            #
                                                                                                                                                                                                                                                      #
   child
                            instance of child
                                                                                                                                                                                                                                                    define parent class
  calls overridden method
```

When the above code is executed, it produces the following result-

```
Calling child method
```

# **Base Overloading Methods**

classes-The following table lists some generic functionality that you can override in your own

SN	Method, Description & Sample Call
1	init( self [,args] ) Constructor (with any optional arguments) Sample Call : obj = className(args)

Л	4	ω	2
cmp ( self, x ) Object comparison Sample Call: cmp(obj, x)	str( self ) Printable string representation Sample Call : $str(obj)$	repr( self ) Evaluatable string representation Sample Call : repr(obj)	del( self ) Destructor, deletes an object Sample Call : del obj

# Overloading Operators

Suppose you have created a Vector class to represent two-dimensional vectors. What happens when you use the plus operator to add them? Most likely Python will yell at you. What

and then the plus operator would behave as per expectation -You could, however, define the \_add\_ \_ method in your class to perform vector addition

### Example

```
print (v1 + v2)
                                                                                                                                                                                                                           #!/usr/bin/python3
                                                                                                                                                                                                           class Vector:
                                                                                     def
                                                                                                                                                                                          def
                                                                                                                                         def
                 Vector(5,-2)
                                  Vector(2,10)
                                                                                                                    return 'Vector (%d, %d)'
                                                                                                                                                        self.b
                                                                                                                                                                         self.a =
                                                                   return Vector(self.a + other.a,
                                                                                                                                                                                         __init__
                                                                                                                                       _str_
                                                                                    _add_
                                                                                                                                                          П
                                                                                                                                     _(self):
                                                                                   (self,other):
                                                                                                                                                         σ
                                                                                                                                                                                        _(self, a, b):
                                                                                                                       %
                                                                                                                       (self.a, self.b)
                                                                    self.b + other.b)
```

When the above code is executed, it produces the following result-

```
Vector(7,8)
```

## **Data Hiding**

directly visible to outsiders. An object's attributes may or may not be visible outside the class definition. You need to name attributes with a double underscore prefix, and those attributes then will not be

### Example

```
print (counter.
                                                   counter.count()
                                                                                                                                                                                                                                                                                                                              #!/usr/bin/python3
                          counter.count()
                                                                                counter = JustCounter()
                                                                                                                                                                                                                                                                          class JustCounter:
                                                                                                                                                                                        def count(self):
                                                                                                                                                                                                                                              _secretCount = 0
                                                                                                                                    print (self.
                                                                                                                                                               _secretCount += 1
_secretCount)
                                                                                                                                   _secretCount)
```

When the above code is executed, it produces the following result-

```
AttributeError: JustCounter instance has no attribute '__secretCount'
                                                                                                                                              Traceback (most recent call last):
                                                                                              File "test.py", line 12, in <module>
                                                print counter.
                                                _secretCount
```

your last line as following, then it works for you-You can access such attributes Python protects those members by internally changing the name to include the class name. as object. className\_ attrName. If you would replace

```
print (counter._JustCounter.
                     _secretCount)
```

When the above code is executed, it produces the following result-

# 20. Python 3 — Regular Expressions

are widely used in UNIX world. strings or sets of strings, using a specialized syntax held in a pattern. Regular expressions A regular expression is a special sequence of characters that helps you match or find other

module raises the exception re.error if an error occurs while compiling or using a regular The module **re** provides full support for Perl-like regular expressions in Python. The **re** 

while dealing with regular expressions, we would use Raw Strings asr'expression'. have special meaning when they are used in regular expression. To avoid any confusion expressions. Nevertheless, a small thing first: There are various characters, which would We would cover two important functions, which would be used to handle regular

# Basic patterns that match single chars

- a, X, 9, < -- ordinary characters just match themselves exactly.
- . (a period) -- matches any single character except newline '\n'
- **\w** -- matches a "word" character: a letter or digit or underbar [a-zA-Z0-9 $_{-}$ ]
- \W -- matches any non-word character.
- **\b** -- boundary between word and non-word
- \s -- matches a single whitespace character -space, newline, return, tab
- \S -- matches any non-whitespace character.
- \t, \n, \r -- tab, newline, return
- \d -- decimal digit [0-9]
- ~ = matches start of the string
- \$ = match the end of the string
- ullet \ -- inhibit the "specialness" of a character.

## **Compilation flags**

short, one-letter form such as I. available in the re module under two names, a long name such as IGNORECASE and a Compilation flags let you modify some aspects of how regular expressions work. Flags are

Flag	Meaning
ASCII, A	Makes several escapes like \w, \b, \s and \d match only on ASCII characters with the respective property.
DOTALL, S	Make, match any character, including newlines
IGNORECASE, I	Do case-insensitive matches

LOCALE, L	Do a locale-aware match
MULTILINE, M	Multi-line matching, affecting ^ and \$
VERBOSE, X (fo	(for Enable verbose REs, which can be organized more cleanly and understandably

# The match Function

This function attempts to match RE pattern to string with optional flags.

Here is the syntax for this function-

```
re.match(pattern,
string,
flags=0)
```

Here is the description of the parameters-

flags You	string This patte	pattern This	Parameter
You can specify different flags using bitwise OR ( ). These are modifiers, which are listed in the table below.	This is the string, which would be searched to match the pattern at the beginning of string.	This is the regular expression to be matched.	Description

The re.match function returns a **match** object on success, **None** on failure. group(num) or groups() function of **match** object to get matched expression. We use

Match Object Methods	Description
group(num=0)	This method returns entire match (or specific subgroup num)
groups()	This method returns all matching subgroups in a tuple (empty if there weren't any)

### Example

line = "Cats are smarter than dogs" #!/usr/bin/python3 import re

```
matchObj = re.match( r'(.*) are (.*?) .*', line, re.M|re.I)
                                                                                                                                                                                                                                                 if matchObj:
print ("No match!!")
                                                                                             print ("matchObj.group(2) : ", matchObj.group(2))
                                                                                                                                           print ("matchObj.group(1) : ", matchObj.group(1))
                                                                                                                                                                                           print ("matchObj.group() : ", matchObj.group())
```

When the above code is executed, it produces the following result-

```
matchObj.group(2) :
                       matchObj.group(1) :
                                                 matchObj.group() :
                                                  Cats are smarter than dogs
                           Cats
   smarter
```

## The search Function

optional flags. function searches for first occurrence 약 RE pattern within the string, with

Here is the syntax for this function-

```
re.search(pattern, string, flags=0)
```

Here is the description of the parameters-

Parameter	Description
pattern	This is the regular expression to be matched.
string	This is the string, which would be searched to match the pattern anywhere in the string.
flags	You can specify different flags using bitwise OR ( ). These are modifiers, which are listed in the table below.

The re.search function returns a **match** object on success, **none** on failure. use group(num) or groups() function of **match** object to get the matched expression. Х е

Match Object Methods	Description
group(num=0)	This method returns entire match (or specific subgroup num)

groups()	This method returns all matching subgroups in a tuple (empty if there weren't any)
	if there weren't any)

#### Example

```
searchObj = re.search( r'(.*) are (.*?) .*', line, re.M|re.I)
                                                                                                                                                                                                                                                                                                                                               line = "Cats are smarter than dogs";
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  #!/usr/bin/python3
                                                                                                                                                                                                                                                                                                                                                                                                                                                   import re
print ("Nothing found!!")
                                                                                                 print ("searchObj.group(2) : ", searchObj.group(2))
                                                                                                                                              print ("searchObj.group(1) : ", searchObj.group(1))
                                                                                                                                                                                            print ("searchObj.group() : ", searchObj.group())
                                                                                                                                                                                                                                                    searchObj:
```

When the above code is executed, it produces following result-

```
matchObj.group(2) :
                        matchObj.group(1) :
                                                 matchObj.group() :
                                                  Cats are smarter than dogs
                          Cats
 smarter
```

## Matching Versus Searching

match anywhere in the string (this is what Perl does by default). Python offers two different primitive operations based on regular expressions: match checks for a match only at the beginning of the string, while search checks for a

#### Example

```
line = "Cats are smarter than dogs";
                                    searchObj = re.search( r'dogs', line, re.M|re.I)
                                                                                                                                                                                                                                                                                                                                                                                                                                     #!/usr/bin/python3
if searchObj:
                                                                                                                                                                                                                    if matchObj:
                                                                                                                                                                                                                                                             matchObj = re.match( r'dogs', line, re.M|re.I)
                                                                                                                                                                                                                                                                                                                                                                                              import re
                                                                                     print ("No match!!")
                                                                                                                                                                        print ("match --> matchObj.group() : ", matchObj.group())
```

```
print ("Nothing found!!")
                                          --> searchObj.group()
                                     . =
                                          searchObj.group())
```

When the above code is executed, it produces the following result-

```
search --> matchObj.group()
                    No match!!
..
dogs
```

## Search and Replace

One of the most important re methods that use regular expressions is sub

#### Syntax

```
re.sub(pattern, repl,
string, max=0)
```

occurrences unless max is provided. This method returns modified string. This method replaces all occurrences of the RE pattern in string with repl, substituting all

#### Example

```
print ("Phone Num : ", num)
                                                                                                                                            print ("Phone Num : ", num)
                                                                      # Remove anything other than digits
                                                                                                                                                                             num = re.sub(r'#.*$', "", phone)
                                                                                                                                                                                                                     # Delete Python-style comments
                                                                                                                                                                                                                                                                                         phone = "2004-959-559 # This is Phone Number"
                                                                                                                                                                                                                                                                                                                                                                import re
                                                                                                                                                                                                                                                                                                                                                                                                    #!/usr/bin/python3
                                    re.sub(r'\D',
                                 "", phone)
```

When the above code is executed, it produces the following result-

```
Phone Num :
2004959559
                   2004-959-559
```

# Regular Expression Modifiers: Option Flags

matching. The modifiers are specified as Regular expression literals may include an optional modifier to control various aspects of an optional flag. You can provide multiple

modifiers using exclusive OR (|), as shown previously and may be represented by one of these-

Modifier	Description
re.I	Performs case-insensitive matching.
re.L	Interprets words according to the current locale. This interpretation affects the alphabetic group (\w and \W), as well as word boundary behavior (\b and \B).
re.M	Makes \$ match the end of a line (not just the end of the string) and makes ^ match the start of any line (not just the start of the string).
re.S	Makes a period (dot) match any character, including a newline.
re.U	Interprets letters according to the Unicode character set. This flag affects the behavior of $\w, \W, \b, \B$ .
re.×	Permits "cuter" regular expression syntax. It ignores whitespace (except inside a set [] or when escaped by a backslash) and treats unescaped # as a comment marker.

## Regular Expression Patterns

Except for the control characters, (+ ? . \*  $^{\circ}$  \$ ( ) [ ] { } | \), all characters match themselves. You can escape a control character by preceding it with a backslash.

The following table lists the regular expression syntax that is available in Python-

Pattern	Description
>	Matches beginning of line.
\$	Matches end of line.
	Matches any single character except newline. Using m option allows it to match newline as well.
[]	Matches any single character in brackets.
[^]	Matches any single character not in brackets

re*	Matches 0 or more occurrences of preceding expression.
re+	Matches 1 or more occurrence of preceding expression.
re?	Matches 0 or 1 occurrence of preceding expression.
re{ n}	Matches exactly n number of occurrences of preceding expression.
re{ n,}	Matches n or more occurrences of preceding expression.
re{ n, m}	Matches at least n and at most m occurrences of preceding expression.
al b	Matches either a or b.
(re)	Groups regular expressions and remembers matched text.
(?imx)	Temporarily toggles on i, m, or $x$ options within a regular expression. If in parentheses, only that area is affected.
(?-imx)	Temporarily toggles off i, m, or x options within a regular expression. If in parentheses, only that area is affected.
(?: re)	Groups regular expressions without remembering matched text.
(?imx: re)	Temporarily toggles on i, m, or ${\sf x}$ options within parentheses.
(?-imx: re)	Temporarily toggles off i, m, or $\boldsymbol{x}$ options within parentheses.
(?#)	Comment.
(?= re)	Specifies position using a pattern. Does not have a range.
(?! re)	Specifies position using pattern negation. Does not have a range.
(?> re)	Matches independent pattern without backtracking.
\w	Matches word characters.

\W	Matches nonword characters.
\s	Matches whitespace. Equivalent to $[\t\n\r\f]$ .
\S	Matches nonwhitespace.
\d	Matches digits. Equivalent to [0-9].
\D	Matches nondigits.
A	Matches beginning of string.
\Z	Matches end of string. If a newline exists, it matches just before newline.
\z	Matches end of string.
\G	Matches point where last match finished.
\b	Matches word boundaries when outside brackets. Matches backspace (0x08) when inside brackets.
\B	Matches nonword boundaries.
\n, \t, etc.	Matches newlines, carriage returns, tabs, etc.
\1\9	Matches nth grouped subexpression.
\10	Matches nth grouped subexpression if it matched already. Otherwise refers to the octal representation of a character code.

## Regular Expression Examples

### Literal characters

Example	Description
python	Match "python".

### Character classes

Example	Description
[Pp]ython	Match "Python" or "python"
rub[ye]	Match "ruby" or "rube"
[aeiou]	Match any one lowercase vowel
[0-9]	Match any digit; same as [0123456789]
[a-z]	Match any lowercase ASCII letter
[A-Z]	Match any uppercase ASCII letter
[a-zA-Z0-9]	Match any of the above
[^aeiou]	Match anything other than a lowercase vowel
[-0-9]	Match anything other than a digit

## Special Character Classes

Example	Description
	Match any character except newline
ργ	Match a digit: [0-9]
۵۱	Match a nondigit: [^0-9]
\s	Match a whitespace character: [ \t\r\n\f]
S\	Match nonwhitespace: [^ \t\r\n\f]
\w	Match a single word character: [A-Za-z0-9_]
W	Match a nonword character: [^A-Za-z0-9_]

### Repetition Cases

Example	Description
ruby?	Match "rub" or "ruby": the y is optional
ruby*	Match "rub" plus 0 or more ys
ruby+	Match "rub" plus 1 or more ys
\d{3}	Match exactly 3 digits
\d{3,}	Match 3 or more digits
\d{3,5}	Match 3, 4, or 5 digits

## Nongreedy Repetition

This matches the smallest number of repetitions-

## **Grouping with Parentheses**

Example	Description
\D\d+	No group: + repeats \d
(\D\d)+	Grouped: + repeats \D\d pair
([Pp]ython(, )?)+	Match "Python", "Python, python, python", etc.

### **Backreferences**

This matches a previously matched group again-

Example	Description
([Pp])ython&\1ails	Match python&pails or Python&Pails
([""])[^\1]*\1	Single or double-quoted string. \1 matches whatever the 1st group matched. \2 matches whatever the 2nd group matched, etc.

### **Alternatives**

Example	Description
python perl	Match "python" or "perl"
rub(y le))	Match "ruby" or "ruble"
Python(!+ \?)	"Python" followed by one or more ! or one ?

### **Anchors**

This needs to specify match position.

Example	Description
^Python	Match "Python" at the start of a string or internal line
Python\$	Match "Python" at the end of a string or line
\APython	Match "Python" at the start of a string
Python\Z	Match "Python" at the end of a string
\bPython\b	Match "Python" at a word boundary
\brub\B	\B is nonword boundary: match "rub" in "rube" and "ruby" but not alone

Python(?=!)	Match "Python", if followed by an exclamation point.
Python(?!!)	Match "Python", if not followed by an exclamation point.

## **Special Syntax with Parentheses**

Example	Description
R(?#comment)	Matches "R". All the rest is a comment
R(?i)uby	Case-insensitive while matching "uby"
R(?i:uby)	Same as above
rub(?:y le))	Group only without creating $ackslash 1$ backreference

# 21. Python 3 – CGI Programming

The Common Gateway Interface, or CGI, is a set of standards that define how information is exchanged between the web server and a custom script. The CGI specs are currently maintained by the NCSA and NCSA.

### What is CGI?

- programs to interface with information servers such as HTTP servers The Common Gateway Interface, 윽 CGI, is ۵ standard for external gateway
- The current version is CGI/1.1 and CGI/1.2 is under progress.

### Web Browsing

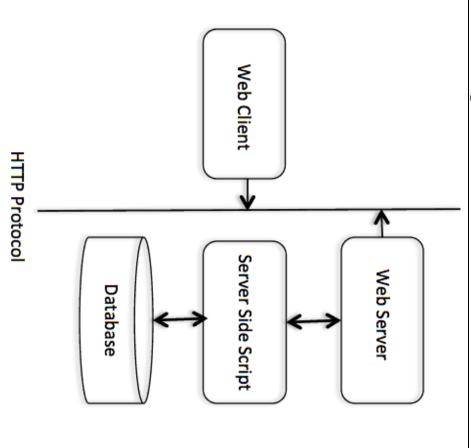

browse a particular web page or URL. To understand the concept of CGI, let us see what happens when we click a hyperlink to

- filename. Your browser contacts the HTTP web server and demands for the URL, i.e.,
- indicating that you requested a wrong file. The web server parses the URL and looks for the filename. If it finds the particular then it sends it back to the browser, otherwise sends an error message
- The web browser takes response from the web server and displays either, the received file or error message.

is called the Common Gateway Interface or CGI and the programs are called CGI scripts. directory is requested that file is not sent back. Instead, it is executed as a program, and However, it is possible to set up the HTTP server so that whenever a file in a certain These CGI programs can be Python Script, PERL Script, Shell Script, C or C++ program, whatever that output of the program, is sent back for your browser to display. This function

## CGI Architecture Diagram

## Web Server Support and Configuration

and it is configured to handle CGI Programs. All the CGI Programs, which are to be executed by the HTTP server, are kept in a pre-configured directory. This directory is called have extension as .cgi, but you can keep your files with python extension .py as well. Before you proceed with CGI Programming, make sure that your Web Server supports CGI CGI Directory and by convention it is named as /var/www/cgi-bin. By convention, CGI files

the following lines in the httpd.conf file By default, the Linux server is configured to run only the scripts in the cgi-bin directory in /var/www. If you want to specify any other directory to run your CGI scripts, comment

```
</Directory>
                                                                                                                                                  <Directory "/var/www/cgi-bin">
                                                         Order allow, deny
                                                                                         Options ExecCGI
                               Allow from all
                                                                                                                       AllowOverride None
```

```
Options All
</Directory>
                                                         <Directory "/var/www/cgi-bin">
```

The following line should also be added for apache server to treat .py file as cgi script.

```
AddHandler cgi-script .py
```

to run any other CGI program like Perl or Shell, etc. Here, we assume that you have Web Server up and running successfully and you are able

### First CGI Program

program, make sure you have changed the mode of file using **chmod 755** the UNIX command to make file executable. Here is a simple link, which is linked to a CGI script called hello.py. /var/www/cgi-bin directory and it has the following content. Before running This file your CGI is kept in hello.py,

```
print ('</html>')
                                                           print
                                                                                                                      print
                                                                                                                                                                                print
                          print ('</body>')
                                                                                         print ('<body>')
                                                                                                                                                print ('<title>Hello Word - First CGI Program</title>')
                                                                                                                                                                                                                                                                                                                                  #!/usr/bin/python3
                                                                                                                                                                                                             print ("<html>")
                                                                                                                                                                                                                                                                      print ("Content-type:text/html")
                                                            ('<h2>Hello Word! This is my first CGI program</h2>')
                                                                                                                      ('</head>')
                                                                                                                                                                              ('<head>')
```

Note: First line in the script must be the path to Python executable. In Linux, it should be #!/usr/bin/python3

Enter the following URL in your browser -

```
http://www.tutorialspoint.com/cgi-bin/hello.py
```

## Hello Word! This is my first CGI program

the screen. There is one important and extra feature available that is the first line to be browser and it specifies the content type to be displayed on the browser screen. printed Content-type:text/html followed by a blank line. This line is sent back to the This hello.py script is a simple Python script, which writes its output on STDOUT file, i.e.,

complicated CGI programs using Python. This script can interact with any other external system also to exchange information such as RDBMS. By now, you must have understood the basic concept of CGI and you can write many

### **HTTP Header**

The line  $Content-type:text/html\r\n\r\n$  is part of HTTP header which is sent to the browser to understand the content. All the HTTP header will be in the following form-

Content-type: text/html\r\n\r\n HTTP Field Name: For Example Field Content

Programming. There are few other important HTTP headers, which you will use frequently in your CGI

Header	Description
Content-type:	A MIME string defining the format of the file being returned. Example is Content-type:text/html
Expires: Date	The date the information becomes invalid. It is used by the browser to decide when a page needs to be refreshed. A valid date string is in the format 01 Jan 1998 12:00:00 GMT.
Location: URL	The URL that is returned instead of the URL requested. You can use this field to redirect a request to any file.
Last-modified: Date	The date of last modification of the resource.
Content-length: N	The length, in bytes, of the data being returned. The browser uses this value to report the estimated download time for a file.
Set-Cookie: String	Set the cookie passed through the <i>string</i>

## **CGI Environment Variables**

play an important role while writing any CGI program. All the CGI programs have access to the following environment variables. These variables

Variable Name	
Description	

CONTENT_TYPE	The data type of the content. Used when the client is sending attached content to the server. For example, file upload.
CONTENT_LENGTH	The length of the query information. It is available only for POST requests.
HTTP_COOKIE	Returns the set cookies in the form of key & value pair.
HTTP_USER_AGENT	The User-Agent request-header field contains information about the user agent originating the request. It is name of the web browser.
PATH_INFO	The path for the CGI script.
QUERY_STRING	The URL-encoded information that is sent with GET method request.
REMOTE_ADDR	The IP address of the remote host making the request. This is useful logging or for authentication.
REMOTE_HOST	The fully qualified name of the host making the request. If this information is not available, then REMOTE_ADDR can be used to get IR address.
REQUEST_METHOD	The method used to make the request. The most common methods are GET and POST.
SCRIPT_FILENAME	The full path to the CGI script.
SCRIPT_NAME	The name of the CGI script.
SERVER_NAME	The server's hostname or IP Address
SERVER_SOFTWARE	SOFTWARE  The name and version of the software the server is running.

Here is a small CGI program to list out all the CGI variables. Click this link to see the result Get Environment.

```
print ()
print ("<font size=+1>Environment</font><\br>";)
                                                        print ("Content-type: text/html")
                                                                                   import os
                                                                                                                #!/usr/bin/python3
```

```
print ("<b>%20s</b>:
                           param in os.environ.keys():
%s<\br>"
   %
 (param, os.environ[param]))
```

## **GET and POST Methods**

GET Method and POST Method. browser uses two methods to pass this information to the web server. These methods are from your browser to web server and ultimately to your CGI Program. Most frequently, You must have come across many situations when you need to pass some information

## Passing Information using GET method

The GET method sends the encoded user information appended to the page and the encoded information are separated by the? character as page request. The follows-

http://www.test.com/cgi-bin/hello.py?key1=value1&key2=value2

- web Location:box. GET method is the default method to pass information from the browser server and ≓ produces a long string that appears in your browser's to the
- Never use GET method if you have password or other sensitive information to pass to the server.
- The GET method has size limtation: only 1024 characters can be sent in a request
- accessible in your CGI Program through QUERY\_STRING environment variable The GET method sends information using QUERY\_STRING header and <u>≶</u> be

or you can use HTML <FORM> tags to pass information using GET method. You can pass information by simply concatenating key and value pairs along with any URL

## Simple URL Example – Get Method

Here is a simple URL, which passes two values to hello\_get.py program using GET method.

```
/cgi-bin/hello_get.py?first_name=Malhar&last_name=Lathkar
```

going to use the **cgi** module, which makes it very easy to access the passed informationbelow is the **hello \_get.py** script to handle the input given by web browser. We are

```
form
                                                                                                                                                              #!/usr/bin/python3
                                                                                import cgi, cgitb
                                                                                                           # Import modules for
                           Create instance of FieldStorage
   п
cgi.FieldStorage()
                                                                                                         CGI handling
```

```
print ("</html>">)
                                                                print ("<h2>Hello %s %s</h2>" % (first_name, last_name))
                                                                                                                                                                                              print ("<head>")
                                  print ("</body>")
                                                                                                 print ("<body>")
                                                                                                                                  print ("</head>")
                                                                                                                                                                 print ("<title>Hello - Second CGI Program</title>")
                                                                                                                                                                                                                                print ("<html>)"
                                                                                                                                                                                                                                                                 print()
                                                                                                                                                                                                                                                                                                print ("Content-type:text/html")
                                                                                                                                                                                                                                                                                                                                                                                                first_name
                                                                                                                                                                                                                                                                                                                                                                 last_name
                                                                                                                                                                                                                                                                                                                                                                                                                                    Get data from fields
                                                                                                                                                                                                                                                                                                                                                                                                = form.getvalue('first_name')
                                                                                                                                                                                                                                                                                                                                                                form.getvalue('last_name')
```

This would generate the following result-

### Hello ZARA ALI

## Simple FORM Example – GET Method

This example passes two values using HTML FORM and submit button. We use the same CGI script hello\_get.py to handle this input.

```
First Name: <input type="text" name="first_name">
                                                   Last Name: <input type="text" name="last_name" />
                                                                                                                                                                                                                      <form action="/cgi-bin/hello_get.py" method="get">
<input type="submit" value="Submit"</pre>
                                                                                                                                                                       <br />
```

Here is the actual output of the above form, you enter the First and the Last Name and then click submit button to see the result.

Last Name: Submit	First Name:

## **Passing Information Using POST Method**

instead of sending it as a text string after a ? in the URL, it sends it as a separate message. This message comes into the CGI script in the form of the standard input. method. This packages the information in exactly the same way as the GET methods, but A generally more reliable method of passing information to a CGI program is the POST

Given below is same hello\_get.py script, which handles GET as well as the POST method.

```
print ("</html>")
                                                                                print
                                                                                                            print
                                                                                                                                                                 print
                                                                                                                                                                                                                                               print ("Content-type:text/html")
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   #!/usr/bin/python3
                                                                                                                                       print ("<title>Hello -
                                                                                                                                                                                            print ("<html>")
                                                                                                                                                                                                                       print()
                                                                                                                                                                                                                                                                                                                                 first_name
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                 import cgi, cgitb
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             # Import modules for CGI handling
                                                                                                                                                                                                                                                                                                                                                              Get data from fields
                                                                                                                                                                                                                                                                                                                                                                                                                                            Create instance of FieldStorage
                                                                                                                                                                ("<head>")
                                                                                ("<body>")
                                                                                                            ("</head>")
                          ("</body>")
                                                      ("<h2>Hello %s %s</h2>"
                                                                                                                                                                                                                                                                                                                                                                                                                  cgi.FieldStorage()
                                                                                                                                                                                                                                                                                                                                 = form.getvalue('first_name')
                                                                                                                                                                                                                                                                                                      form.getvalue('last_name')
                                                                                                                                       Second CGI Program</title>")
                                                   % (first_name, last_name))
```

FORM and the submit button. We use the same CGI script hello\_get.py to handle this again take the same example as above, which passes two values using the HTML

```
</form>
                                                        <input type="submit" value="Submit"</pre>
                                                                                                                                                                         Last Name: <input type="text" name="last_name"
                                                                                                                                                                                                                                           First Name: <input type="text" name="first_name"><br />
                                                                                                                                                                                                                                                                                               <form action="/cgi-bin/hello_get.py" method="post">
```

then click the submit button to see the result. Here is the actual output of the above form. You enter the First and the Last Name and

_ast Name:	irst Name:
Submit	

## Passing Checkbox Data to CGI Program

Checkboxes are used when more than one option is required to be selected.

Here is an HTML code example for a form with two checkboxes-

```
<input
<input type="submit" value="Select Subject"</pre>
                                                                       <input
                                                                                                       <form action="/cgi-bin/checkbox.py"</pre>
                                   type="checkbox"
                                                                     type="checkbox"
                                   name="physics" value="on"
                                                                        name="maths" value="on" /> Maths
                                                                                                    method="POST" target="_blank">
                                     /> Physics
```

The result of this code is in the above form-

□ Maths	
Physics	
Select Subject	

Given below is the checkbox button. checkbox.cgi script to handle the input given by web browser ę

```
form =
                                                                                                                                                   냒
                                                                                                                                                                                                                                                                                                                          # Import modules for
                         if form.getvalue('physics'):
                                                                                                                                                                                                                                                                                                                                                                         #!/usr/bin/python3
                                                                                                                                                                          Get data from fields
                                                                                                                                                                                                                                                Create instance of FieldStorage
                                                                                                                                                 form.getvalue('maths'):

                                                                                                                                                                                                                                                                            print ("<html>")
                                                                                                                                                                                                                                                                                                                                                                                                                 physics_flag
                                                                    ("<h2> CheckBox Physics is : %s</h2>" % physics_flag)
                                                                                                                                                                                                                                                                                                                                                                                                                    "OFF"
```

# Passing Radio Button Data to CGI Program

Radio Buttons are used when only one option is required to be selected

Here is an HTML code example for a form with two radio buttons-

```
<input type="submit" value="Select Subject" />
                                                                     <input type="radio" name="subject" value="physics"</pre>
                                                                                                                                 <input type="radio" name="subject" value="maths" /> Maths
                                                                                                                                                                                                 <form action="/cgi-bin/radiobutton.py" method="post" target="_blank">
                                                                          /> Physics
```

The result of this code is the following form-

Below is radiobutton.py script to handle input given by web browser for radio button-

```
÷
                               # Get data from fields
                                                                                                  form = cgi.FieldStorage()
                                                                                                                                     # Create instance of FieldStorage
                                                                                                                                                                                                     import cgi, cgitb
                                                                                                                                                                                                                                                                                                            #!/usr/bin/python3
                                                                                                                                                                                                                                         Import modules for CGI handling
form.getvalue('subject'):
```

```
print ("</html>")
                              print
                                                     print ("<h2> Selected Subject is %s</h2>" % subject)
                                                                                print
                                                                                                        print ("</head>")
                                                                                                                                                             print ("<head>")
                                                                                                                                     print ("<title>Radio -
                                                                                                                                                                                         print ("<html>")
                                                                                                                                                                                                                    print()
                                                                                                                                                                                                                                               print "Content-type:text/html")
                                                                                                                                                                                                                                                                                                  subject =
                                                                                ("<body>")
                             ("</body>")
                                                                                                                                                                                                                                                                                                                                                    form.getvalue('subject')
                                                                                                                                     Fourth CGI Program</title>")
```

## Passing Text Area Data to CGI Program

TEXTAREA element is used when multiline text has to be passed to the CGI Program.

Here is an HTML code example for a form with a TEXTAREA box-

```
Type your text here...
</form>
                               <input type="submit"</pre>
                                                                     </textarea>
                                                                                                                                        <textarea name="textcontent"</pre>
                                                                                                                                                                           <form action="/cgi-bin/textarea.py" method="post"</pre>
                                   value="Submit"
                                                                                                                                        cols="40" rows="4">

## Using Cookies in CGI

session information among different pages. For example, one user registration ends after completing many pages. How to maintain user's session information across all the web HTTP protocol is a stateless protocol. For a commercial website, it is required to maintain

visitor experience or site statistics. tracking preferences, purchases, commissions, and other information required for better In many situations, using cookies is the most efficient method of remembering and

### How It Works?

may accept the cookie. If it does, it is stored as a plain text record on the visitor's hard drive. Now, when the visitor arrives at another page on your site, the cookie is available for retrieval. Once retrieved, your server knows/remembers what was stored. Your server sends some data to the visitor's browser in the form of a cookie. The browser

Cookies are a plain text data record of five variable-length fields-

the visitor quits the browser. **Expires:** The date the cookie will expire. If this is blank, the cookie will expire when

- Domain: The domain name of your site.
- blank if you want to retrieve the cookie from any directory or page. Path: The path to the directory or web page that sets the cookie. This may be
- Secure: If this retrieved with a secure server. If this field is blank, no such restriction exists. field contains the word "secure", then the cookie may only be
- Name=Value: Cookies are set and retrieved in the form of key and value pairs

## Setting up Cookies

Header before the Content-type field is sent. Assuming you want to set the User ID and Password as cookies, Cookies are set as follows-It is very easy to send cookies to the browser. These cookies are sent along with the HTTP

```
print ("Content-type:text/html\r\n\r\n")
                                                                                                                                                                                                                                                                                                                                             print ("Set-Cookie:UserID=XYZ;\r\n")
                                                                                                                                                                                                                                                                                                                                                                                                                                                           #!/usr/bin/python3
..........Rest of the HTML Content....
                                                                                                                                                                                                                            ("Set-Cookie:Expires=Tuesday, 31-Dec-2007 23:12:40 GMT";\r\n")
                                                                                                                ("Set-Cookie:Path=/perl;\n")
                                                                                                                                                                          ("Set-Cookie:Domain=www.tutorialspoint.com;\r\n")
                                                                                                                                                                                                                                                                                      ("Set-Cookie:Password=XYZ123;\r\n")
```

Cookie HTTP header to set the cookies. From this example, you must have understood how ç set cookies. Хе esu Set-

It is optional to set cookies attributes like Expires, Domain, and Path. It is notable that the cookies are set before sending the magic line "Content-type:text/html\r\n\r\n.

## Retrieving Cookies

It is very easy to retrieve all the set cookies. Cookies are variable HTTP\_COOKIE and they will have the following formstored 3 CGI environment

```
key1=value1;key2=value2;key3=value3....
```

Here is an example of how to retrieve cookies-

```
import cgi,
                             from os import environ
                                                                                                                  #!/usr/bin/python3
                                                       Import modules for CGI handling
cgitb
```

```
print
print
                                                                                                                                                                                                            냙
                                                                                                                                                                                                         environ.has_key('HTTP_COOKIE'):
                                                                                                                                                                                 for cookie in map(strip,
("Password
                     ("User ID
                                                                    ή
                                                                                                                                        if key == "UserID":
                                                                                                                                                           (key, value ) = split(cookie, '=');
                                                                    key == "Password":
                                              password = value
                                                                                                                 user_id = value
                     = %s" % user_id)
%s"
% password)
                                                                                                                                                                                 split(environ['HTTP_COOKIE'], ';')):
```

This produces the following result for the cookies set by the above script-

```
Password = XYZ123
                            User ID = XYZ
```

## File Upload Example

To upload a file, the HTML form must have the enctype attribute set to **multipart/form-data**. The input tag with the file type creates a "Browse" button.

```
<html>
</html>
                        </body>
                                                   </form>
                                                                           <input
                                                                                                    File:

                                                                                                                                                                                                                                                                                               +
                                                                                                                                                                                                                                                                                              fn +
                                                                                                                                                                                                                                                                                                 :
                                                                                                                                                                                                                                                                                             was uploaded successfully'
```

separator as follows, otherwise on your windows machine above open() statement should work fine. If you run the above script on Unix/Linux, then you need to take care of replacing file

```
fn
   П
os.path.basename(fileitem.filename.replace("\\",
     <u>"</u>
```

# How To Raise a "File Download" Dialog Box?

different from the header mentioned in the previous section. Sometimes, it is desired that you want to give an option where a user can click a link and it will pop up a "File Download" dialogue box to the user instead of displaying actual content. This is very easy and can be achieved through HTTP header. This HTTP header is

syntax is as follows-For example, if you want make a FileName file downloadable from a given link, then its

```
print ("Content-Disposition: attachment; filename=\"FileName\"\r\n\n")
                                                                                                                                 print (str)
                                                                                                                                                                           str = fo.read()
                                                                                                                                                                                                                                                          fo = open("foo.txt", "rb")
                                                                                                                                                                                                                                                                                                         # Actual File Content will go hear.
                                                                                                                                                                                                                                                                                                                                                                                                                                        print ("Content-Type:application/octet-stream; name=\"FileName\"\r\n")
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      # HTTP Header
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                         #!/usr/bin/python3
fo.close()
                                          # Close opened file
```

# Python 3 — MySQL Database Access

interfaces adhere to this standard. The Python standard for database interfaces is the Python DB-API. Most Python database

wide range of database servers such as You can choose the right database for your application. Python Database API supports a

- GadFly
- mSQL
- MySQL
- PostgreSQL
- Microsoft SQL Server 2000
- Informix
- Interbase
- Oracle
- Sybase

SQLite

Here is the list of available Python database interfaces: Python Database Interfaces and must download both the Oracle and the MySQL database modules. For example, if you need to access an Oracle database as well as a MySQL database, you APIs. You must download a separate DB API module for each database you need to access.

structures and syntax wherever possible. This API includes the following: The DB API provides a minimal standard for working with databases using Python

- Importing the API module.
- Acquiring a connection with the database.
- Issuing SQL statements and stored procedures.
- Closing the connection

Python 3. Instead, we shall use PyMySQL module. using MySQL. MySQLdb module, a popular interface with MySQL is not compatible with Python has an in-built support for SQLite. In this section, we would learn all the concepts

## What is PyMySQL?

library. The goal of PyMySQL is to be a drop-in replacement for MySQLdb. PyMySQL is an interface for connecting to a MySQL database server from Python. It implements the Python Database API v2.0 and contains a pure-Python MySQL client

## How do I Install PyMySQL?

Before proceeding further, you make sure you have PyMySQL installed on your machine. Just type the following in your Python script and execute it-

```
#!/usr/bin/python3
import PyMySQL
```

If it produces the following result, then it means MySQLdb module is not installed-

```
ImportError: No module named PyMySQL
                                                                                                                                              Traceback (most recent call last):
                                                                                           File "test.py", line 3, in <module>
                                                Import PyMySQL
```

The last stable release is available on PyPI and can be installed with pip:

```
pip install
PyMySQL
```

Alternatively (e.g. if pip is not available), a tarball can be downloaded from GitHub and installed with Setuptools as follows-

```
₩
                                                                                           ₩
                         python setup.py install
# The folder PyMySQL* can be safely removed now
                                                             cd PyMySQL*
                                                                                        curl -L https://github.com/PyMySQL/PyMySQL/tarball/pymysql-X.X |
                                                                                                                      # X.X is the desired PyMySQL version (e.g.
                                                                                                                           0.5
                                                                                                                           or 0.6).
                                                                                             tar
                                                                                             X
```

Note: Make sure you have root privilege to install the above module

## **Database Connection**

Before connecting to a MySQL database, make sure of the following points-

- You have created a database TESTDB.
- You have created a table EMPLOYEE in TESTDB
- This table has fields FIRST\_NAME, LAST\_NAME, AGE, SEX and INCOME.
- User ID "testuser" and password "test123" are set to access TESTDB.
- Python module PyMySQL is installed properly on your machine
- You have gone through MySQL tutorial to understand MySQL Basics.

### Example

Following is an example of connecting with MySQL database "TESTDB"-

```
print ("Database version :
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                # Open database connection
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            #!/usr/bin/python3
db.close()
                                                                                                                                                                                                                                                                                                               cursor.execute("SELECT VERSION()")
                                                                                                                                                                                                                                                                                                                                                                                                                                        cursor = db.cursor()
                                                                                                                                                                                                                                                                                                                                                                                                                                                                             # prepare a cursor object using cursor() method
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      db = PyMySQL.connect("localhost","testuser","test123","TESTDB"
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     import PyMySQL
                                    disconnect from server
                                                                                                                                                                                                                                    Fetch a single row using fetchone() method.
                                                                                                                                                                                                                                                                                                                                                       execute SQL query using execute() method.
                                                                                                                                                                                               cursor.fetchone()
                                                                                                                     %
                                                                                                                            =
                                                                                                                     %
```

While running this script, it produces the following result-

```
Database
version
5.5.20-log
```

and saved into **db** for further use, otherwise **db** is set to None. Next, **db** object is used to create a **cursor** object, which in turn is used to execute SQL queries. Finally, before coming out, it ensures that the database connection is closed and resources are released. If a connection is established with the datasource, then a Connection Object is returned

## **Creating Database Table**

the database tables using **execute** method of the created cursor. Once a database connection is established, we are ready to create tables or records into

#### Example

Let us create a Database table EMPLOYEE-

```
#!/usr/bin/python3
import PyMySQL
```

```
cursor.execute("DROP TABLE IF EXISTS EMPLOYEE")
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          db = PyMySQL.connect("localhost","testuser","test123","TESTDB" )
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                         # Open database connection
db.close()
                                                                                       cursor.execute(sql)

                                                                                              db.rollback()
```

#### Example

directly-The following code segment is another form of execution where you can pass parameters

```
password = "password"
                                                                                                                                                       user_id =
con.execute('insert into Login values("%s", "%s")' %
                                                                                                                                                           "test123"
                              (user_id, password))
```

### **READ Operation**

database. READ Operation on any database means to fetch some useful information from the

or fetchall() method to fetch multiple values from a database table. Once the database connection is established, you are ready to make a database. You can use either **fetchone()** method to fetch a fetch query into this single record

- fetchone(): It fetches the next row of a query result set. A result set is an object that is returned when a cursor object is used to query a table.
- fetchall(): It fetches all the rows in a result set. If some rows have already been extracted from the result set, then it retrieves the remaining rows from the result
- affected by an execute() method. rowcount: This is a read-only attribute and returns the number of rows that were

### Example

than 1000-The following procedure queries all the records from EMPLOYEE table having salary more

```
try:
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   sql =
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     # Prepare SQL query to INSERT a record into
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             #!/usr/bin/python3

```

This will produce the following result-

```
fname=Mac,
lname=Mohan,
age=20,
 sex=M,
 income=2000
```

### Update Operation

UPDATE Operation on any database already available in the database. means to update one or more records, which are

AGE of all the males by one year. The following procedure updates all the records having SEX as 'M'. Here, we increase the

### Example

```
#!/usr/bin/python3
                                          # disconnect from server
                                                                                                                                                                                                           except:
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                         # Prepare SQL query to UPDATE required records
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  # prepare a cursor object using cursor() method

                                                                                                                                                                                                                                                                                                                                                                                                                                                            WHERE SEX = "c" % ("M")
                                                                                                                                                                  is any error
```

## **DELETE Operation**

DELETE operation is required when you want to delete some records from your database. Following is the procedure to delete all the records from EMPLOYEE where AGE is more than 20-

#### Example

```
sql =
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     #!/usr/bin/python3
                                   # disconnect from server
                                                                                                                                                                                                                                                                                                                                                                                                                                       # Prepare SQL query to DELETE required records
db.close()

                                                                                                                                             # Rollback in case there
                                                                                                                                                                                                                                                   # Commit your changes
                                                                                                          db.rollback()
                                                                                                                                                                                                                                                                                          cursor.execute(sql)
                                                                                                                                                                                                                                                                                                                             # Execute the SQL command
                                                                                                                                                                                                                                                                                                                                                                                                      "DELETE FROM EMPLOYEE WHERE AGE >
                                                                                                                                                                                                                                                         in the database
                                                                                                                                            is any error
                                                                                                                                                                                                                                                                                                                                                                                                      '%d'" % (20)
```

## Performing Transactions

Transactions are a mechanism following four propertiesthat ensure data consistency. Transactions have the

- Atomicity: Either a transaction completes or nothing happens at all.
- Ξ. Consistency: A transaction must start in a consistent state and leave the system a consistent state
- transaction. **Isolation:** Intermediate results of a transaction are not visible outside the current

after a system failure. **Durability:** Once a transaction was committed, the effects are persistent, even

The Python DB API 2.0 provides two methods to either *commit* or *rollback* a transaction.

#### Example

You already know how to implement transactions. Here <u>s</u> a similar example

```
sq1 =
                                                                                                                                                                                                                                 # Prepare SQL
                           # Rollback in case there
                                                                            db.commit()
db.rollback()
                                                                                                   # Commit your changes
                                                                                                                             cursor.execute(sql)
                                                                                                                                                     Execute the SQL command
                                                                                                                                                                                                         "DELETE FROM EMPLOYEE WHERE AGE >
                                                                                                                                                                                                                                query
                                                                                                                                                                                                                                to DELETE required records
                                                                                                    in the database
                        is
                           any error
                                                                                                                                                                                                        "'b%'
                                                                                                                                                                                                         (20)
```

### **COMMIT Operation**

Commit is an operation, which gives a green signal to the database to finalize the and after this operation, no change can be reverted back. changes,

Here is a simple example to call the **commit** method.

```
db.commit()
```

## **ROLLBACK Operation**

If you are not satisfied with one or more of the changes and you want to revert back those changes completely, then use the **rollback()** method.

Here is a simple example to call the rollback() method

```
db.rollback()
```

## **Disconnecting Database**

disconnect the Database connection, use the close() method

```
db.close()
```

outstanding transactions are rolled back by the DB. However, instead of depending on any If the connection to a database is closed by the user with the close() method, any

commit or rollback explicitly. of the DB lower level implementation details, your application would be better off calling

#### **Handling Errors**

There are many sources of errors. A few examples are a syntax error in an executed SQL statement, a connection failure, or calling the fetch method for an already cancelled or finished statement handle.

The DB API defines a number of errors that must exist in each database module. The following table lists these exceptions.

Your Python scripts should handle these errors, but before using any of the above exceptions, make sure your MySQLdb has support for that exception. You can get more information about them by reading the DB API 2.0 specification.

# 23. Python 3 — Network Programming

implement clients and servers for both connection-oriented and connectionless protocols. Python provides two levels of access to the network services. At a low level, you can access the basic socket support in the underlying operating system, which allows you to

Python also has libraries that provide higher-level access to specific application-level network protocols, such as FTP, HTTP, and so on.

Socket Programming. This chapter gives you an understanding on the most famous concept in Networking

#### What is Sockets?

communicate within a process, processes on different continents. are the endpoints of ۵ between processes on the same machine, bidirectional communications channel. Sockets may or between

Sockets may be implemented over a number of different channel types: Unix domain sockets, TCP, UDP, and so on. The *socket* library provides specific classes for handling the common transports as well as a generic interface for handling the rest.

Sockets have their own vocabulary-

A zero-length string, which specifies INADDR_ANY, or	
A string " <broadcast>", which specifies an INADDR_BROADCAST address.</broadcast>	
A string, which can be a host name, a dotted-quad address, or an IPV6 address in colon (and possibly dot) notation	
The identifier of a network interface:	hostname
Typically zero, this may be used to identify a variant of a protocol within a domain and type.	protocol
The type of communications between the two endpoints, typically SOCK_STREAM for connection-oriented protocols and SOCK_DGRAM for connectionless protocols.	type
The family of protocols that is used as the transport mechanism. These values are constants such as AF_INET, PF_INET, PF_UNIX, PF_X25, and so on.	domain
Description	Term

port  Each server listens for clients calling on one or more ports. A port may be a Fixnum port number, a string containing a port number, or the
---

### The socket Module

To create a socket, you must use the socket.socket() function socket module, which has the general syntaxavailable Ξ. the

```
socket.socket (socket_family, socket_type, protocol=0)
```

Here is the description of the parameters-

- socket\_family: This is either AF\_UNIX or AF\_INET, as explained earlier.
- socket\_type: This is either SOCK\_STREAM or SOCK\_DGRAM.
- **protocol:** This is usually left out, defaulting to 0.

Once you have socket object, then you can use the required functions to create your client or server program. Following is the list of functions required-

## Server Socket Methods

Method	Description
s.bind()	This method binds address (hostname, port number pair) to socket.
s.listen()	This method sets up and start TCP listener.
s.accept()	This passively accept TCP client connection, waiting until connection arrives (blocking).

## **Client Socket Methods**

Method	Description
s.connect()	This method actively initiates TCP server connection.

## **General Socket Methods**

Method	Description
s.recv()	This method receives TCP message
s.send()	This method transmits TCP message
s.recvfrom()	This method receives UDP message
s.sendto()	This method transmits UDP message
s.close()	This method closes socket
socket.gethostname()	Returns the hostname.

#### A Simple Server

To write Internet servers, we use the **socket** function available in socket module to create a socket object. A socket object is then used to call other functions to setup a socket server.

Now call the bind(hostname, port) function to specify a port for your service on the given host.

connects to the port you specified, and then returns a connection object that represents Next, call the accept method of the returned object. the connection to that client. This method waits until a client

```
# get local machine name
port =
                                                            host =
                                                                                                                                                                                     serversocket = socket.socket(
                                                                                                                                                                                                                                                                                                             #!/usr/bin/python3
                                                                                                                                                                                                                                                                                 import socket
                                                                                                                                                                                                                   create a socket object
                                                        socket.gethostname()
                                                                                                                                                  socket.AF_INET, socket.SOCK_STREAM)
                                                                                                                                                                                                                                                                                                            This is server.py file
```

```
while True:
                                                                                                                                                                                                                                                                                                                                                                                                                                                serversocket.listen(5)

                                                                                                                                                                                                                                                                                                                                                                                                                                                                                         queue up to 5 requests
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              bind
                                     clientsocket.send(msg.encode('ascii'))
                                                                                   msg='Thank you for connecting'+ "\r\n"
                                                                                                                                                                                                                                                                                                              # establish a connection
clientsocket.close()
                                                                                                                                                                             print("Got a connection from %s" % str(addr))
                                                                                                                                                                                                                                                                   clientsocket,addr = serversocket.accept()
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          to the port
```

#### A Simple Client

and a given host. It is very Python's socket module function. Let us write a very simple client program, which opens a connection to a given port 12345 Ħ very simple 6 create ۵ socket client using the

The **socket.connect(hosname, port)** opens a TCP connection to *hostname* on the *port*. Once you have a socket open, you can read from it like any IO object. When done, remember to close it, as you would close a file.

The following code is a very simple client that connects to a given host and port, reads any available data from the socket, and then exits-

```
s.close()
                                                                      # Receive no more than 1024 bytes
                                                                                                        s.connect((host, port))
                                                                                                                                                                                 port = 9999
                                                                                                                                                                                                                   host = socket.gethostname()
                                                                                                                                                                                                                                                        # get local machine name
                                                                                                                                                                                                                                                                                                                             # create a socket object
                                                                                                                                                                                                                                                                                                                                                                                                  #!/usr/bin/python3
                                 msg = s.recv(1024)
                                                                                                                                                                                                                                                                                                                                                                  import socket
                                                                                                                                             connection to hostname on the port.
                                                                                                                                                                                                                                                                                      socket.socket(socket.AF_INET, socket.SOCK_STREAM)
                                                                                                                                                                                                                                                                                                                                                                                                       This
                                                                                                                                                                                                                                                                                                                                                                                                  is client.py file
```

```
print (msg.decode('ascii'))
```

result. Now run this server.py in the background and then run the above client.py ţ see the

```
$ python client.py
                                            # Once server is started run client as follows:
                                                                                           $ python server.py &
                                                                                                                                      Following would start a server in background.
```

This would produce the following result-

```
Thank you for connecting
                                                                              On client terminal
                                                                                                            Got a connection from ('192.168.1.10', 3747)
                                                                                                                                                                                      on server terminal
```

## **Python Internet Modules**

A list of some important modules in Python Network/Internet programming below. are given

Protocol	Common function	Port No	Python module
НПР	Web pages	80	httplib, urllib, xmlrpclib
NNTP	Usenet news	119	nntplib
FTP	File transfers	20	ftplib, urllib
SMTP	Sending email	25	smtplib
POP3	Fetching email	110	poplib
IMAP4	Fetching email	143	imaplib
Telnet	Command lines	23	telnetlib
Gopher	Document transfers	70	gopherlib, urllib

protocols. Please check all the libraries mentioned above to work with FTP, SMTP, POP, and IMAP

### **Further Readings**

This was a quick start with the Socket Programming. It is recommended to go through the following link to find more detaila vast subject. It is

- Unix Socket Programming.

  Python Socket Library and Modules.

# 24. Python 3 — Sending Email using SMTP

routing e-mail between mail servers. Simple Mail Transfer Protocol (SMTP) is a protocol, which handles sending an e-mail and

Python provides smtplib module, which defines an SMTP client session object that can be used to send mails to any Internet machine with an SMTP or ESMTP listener daemon.

mail-Here is a simple syntax to create one SMTP object, which can later be used to send an e-

```
smtpObj = smtplib.SMTP( [host [, port [, local_hostname]]] )
                                             smtplib
```

Here is the detail of the parameters-

- host or a domain name like tutorialspoint.com. This is an optional argument. host: This is the host running your SMTP server. You can specifiy IP address of the
- **port:** If you are providing *host* argument, then you need to specify a port, where SMTP server is listening. Usually this port would be 25.
- local\_hostname: If your SMTP server is running on your local machine, then you can specify just localhost as the option.

the work of mailing a message. It takes three parameters-An SMTP object has an instance method called sendmail, which is typically, used to do

- The sender A string with the address of the sender.
- The receivers A list of strings, one for each recipient.
- The message A message as a string formatted as specified in the various RFCs.

#### Example

Here is a simple way to send one e-mail using Python script. Try it once

```
Subject:
                                                                                                                                                                                                                                                                                                                                     #!/usr/bin/python3
                                   To: To Person <to@todomain.com>
                                                                       message ="""From: From Person <from@fromdomain.com>
                                                                                                                                                 receivers
                                                                                                                                                                                     sender ='from@fromdomain.com'
                                                                                                                                                                                                                                                             import smtplib
                                                                                                                                               =['to@todomain.com']
 e-mail test
```

```
try:
                                                                                                                                                                                                                                                              This
print ("Error: unable to send email")
                                                                      print ("Successfully sent email")

                                                                                                                                                                                                                                                                                                                                                                                                                                                                  text/html
                                                                                                                                                                                                                                                                                                                                                                   to be sent in HTML format
                                                                                               receivers,
                                                                                                    message)
```

## Sending Attachments as an E-mail

To send an e-mail with mixed content requires setting the **Content-type** header to **multipart/mixed**. Then, the text and the attachment sections can be specified within boundaries.

in the message part of the e-mail. A final boundary denoting the e-mail's final section must also end with two hyphens. A boundary is started with two hyphens followed by a unique number, which cannot appear

encoding before transmission. The attached files should be encoded with the pack("m") function to have base 64

#### Example

Following is an example, which sends a file /tmp/test.txt as an attachment. Try it once-

```
import
                                                # Read a file and encode it
                                                                                             filename = "/tmp/test.txt"

# 25. Python 3 — Multithreaded Programming

with the following benefits-Running several threads is similar to running several different programs concurrently, but

- Multiple threads within a process share the same data space with the main thread than if they were separate processes. and can therefore share information or communicate with each other more easily
- memory overhead; they are cheaper than processes. Threads are sometimes called light-weight processes and they do not require much

pointer that keeps track of where within its context is it currently running A thread has a beginning, an execution sequence, and a conclusion. It has an instruction

- It can be pre-empted (interrupted).
- It can temporarily be put on hold (also known as sleeping) while other threads running - this is called yielding.

There are two different kind of threads-

- kernel thread
- user thread

implemented in the kernel. Kernel Threads are a part of the operating system, while the User-space threads are not

are two modules, which support the usage of threads in Python3.

- \_thread
- threading

use the threading module instead. Hence, in Python 3, the module "thread" is not available anymore. However, The thread module has been "deprecated" for quite a long time. Users are encouraged to it has been renamed to "\_thread" for backward compatibilities

## Starting a New Thread

To spawn another thread, you need to call the following method available in the thread

```
_thread.start_new_thread ( function, args[,
kwargs] )
```

Windows This method call enables а fast and efficient way to create new threads ⊒. both Linux and

The method call returns immediately and the child thread starts and calls function with the passed list of *agrs*. When the function returns, the thread terminates.

Here, args is a tuple of arguments; use an empty tuple to call function without passing any arguments. kwargs is an optional dictionary of keyword arguments.

#### Example

```
try:
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            import
                                                                                                                                                                                                                                                  # Create two threads as follows
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        #!/usr/bin/python3

```

Program goes in an infinite loop. You will have to press ctrl-c to stop

compared to the newer threading module Although it is very effective for low-level threading, the thread module is very limited

## The Threading Module

level support for threads than the thread module discussed in the previous section. The newer threading module included with Python 2.4 provides much more powerful, high-

additional methods: The threading module exposes all the methods of the thread module and provides some

- threading.activeCount(): Returns the number of thread objects that are active.
- thread control. threading.currentThread(): Returns the number of thread objects in the caller's
- threading.enumerate(): Returns a list of all the thread objects that are currently

In addition to the methods, the threading module has the *Thread* class that implements threading. The methods provided by the *Thread* class are as follows:

- run(): The run() method is the entry point for a thread.
- start(): The start() method starts a thread by calling the run method
- join([time]): The join() waits for threads to terminate
- isAlive(): The isAlive() method checks whether a thread is still executing
- **getName():** The getName() method returns the name of a thread.
- **setName():** The setName() method sets the name of a thread

# **Creating Thread Using Threading Module**

To implement a new thread using the threading module, you have to do the following

- Define a new subclass of the Thread class.
- Override the \_init\_ .(self [,args]) method to add additional arguments
- do when started. Then, override the run(self [,args]) method to implement what the thread should

Once you have created the new *Thread* subclass, you can create an instance of it and then start a new thread by invoking the *start()*, which in turn calls the *run()*method.

#### Example

#!/usr/bin/python3

```
print ("Exiting Main Thread")
                                                                                       thread2.start()
                              thread2.join()
                                                           thread1.join()
                                                                                                                     thread1.start()
                                                                                                                                                                                                             thread2 = myThread(2,
                                                                                                                                                                                                                                         thread1 =
                                                                                                                                                                                                                                                                      # Create new threads
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              def print_time(threadName, delay, counter):

## Synchronizing Threads

mechanism that allows you to synchronize threads. A new lock is created by calling the Lock() method, which returns the new lock. threading module provided with Python includes а simple-to-implement locking

The acquire(blocking) method of the new lock object is used to force the threads to run synchronously. The optional blocking parameter enables you to control whether the thread waits to acquire the lock.

If blocking is set to 0, the thread returns immediately with a 0 value if the lock cannot be and wait for the lock to be released. acquired and with a 1 if the lock was acquired. If blocking is set to 1, the thread blocks

required. The release() method of the new lock object is used to release the lock when it is no longer

#### Example

```
import
                                                                                                                                                                                                                                                                                                                                                                             #!/usr/bin/python3

## **Multithreaded Priority Queue**

The *Queue* module allows you to create a new queue object that can hold number of items. There are following methods to control the Queue – ۵ specific

- get(): The get() removes and returns an item from the queue.
- put(): The put adds item to a queue.
- qsize(): The qsize() returns the number of items that are currently in the queue.
- empty(): The empty() returns True if queue is empty; otherwise, False.
- full(): the full() returns True if queue is full; otherwise, False.

#### Example

```
#!/usr/bin/python3

# Python 3 — XML Processing

developmental language. XML is a portable, open source language that allows programmers to develop applications that can be read by other applications, regardless of operating system and/or

#### What is XML?

standard. The Extensible Markup Language (XML) is a markup language much like HTML or SGML. This is recommended by the World Wide Web Consortium and available as an open

requiring an SQL- based backbone XML is extremely useful for keeping track of small to medium amounts of data without

## XML Parser Architectures and APIs

The Python standard library provides a minimal but useful set of interfaces to work with

The two most basic and broadly used APIs to XML data are the SAX and DOM interfaces.

- it from the disk and the entire file is never stored in the memory. documents are large or you have memory limitations, it parses the file as it reads and then let the parser proceed through the document. This is useful when your Simple API for XML (SAX): Here, you register callbacks for events of interest
- Document Object Model (DOM) API: This is a World Wide Web Consortium hierarchical (tree-based) form to represent all the features of an XML document. recommendation wherein the entire file is read into the memory and stored in a

On the other hand, using DOM exclusively can really kill your resources, especially if used SAX obviously cannot process information as fast as DOM, when working with large files.

SAX is read-only, while DOM allows changes to the XML file. Since these two different APIs large projects literally complement each other, there is no reason why you cannot use them both for

For all our XML code examples, let us use a simple XML file movies.xml as an input-

## Parsing XML with SAX APIs

SAX is a standard interface for event-driven XML parsing. Parsing XML with SAX generally requires you to create your own ContentHandler by subclassing xml.sax.ContentHandler.

parser calls ContentHandler methods as it parses the XML file. ContentHandler object provides methods Your ContentHandler handles the particular tags and attributes of your flavor(s) of XML. A to handle various parsing events. Its owning

parameter text. The methods startDocument and endDocument are called at the start and the end of the XML file. The method characters(text) is passed the character data of the XML file via the

namespace mode, the The ContentHandler is called at the start and end of each element. If the parser is not in methods startElement(tag, attributes) andendElement(tag) are

called. Here, tag is the element tag, and attributes is an Attributes object. otherwise, the corresponding methods start Element NS and end Element NS are

Here are other important methods to understand before proceeding-

## The make\_parser Method

The following method creates a new parser object and returns it. The parser object created will be of the first parser type, the system finds.

```
xml.sax.make_parser( [parser_list] )
```

Here is the detail of the parameters-

**parser\_list:** The optional argument consisting of a list of parsers to use, which must all implement the make\_parser method.

### The parse Method

The following method creates a SAX parser and uses ≓ ç parse മ document

```
xml.sax.parse( xmlfile, contenthandler[, errorhandler])
```

Here are the details of the parameters-

- xmlfile: This is the name of the XML file to read from.
- contenthandler: This must be a ContentHandler object.
- errorhandler: If specified, errorhandler must be a SAX ErrorHandler object.

## The parseString Method

There is one more method to create a SAX parser and to parse the specified**XML** . string.

```
xml.sax.parseString(xmlstring,
 contenthandler[,
errorhandler])
```

Here are the details of the parameters-

- xmlstring: This is the name of the XML string to read from.
- contenthandler: This must be a ContentHandler object.
- errorhandler: If specified, errorhandler must be a SAX ErrorHandler object.

#### Example

#!/usr/bin/python3 import xml.sax

```
class MovieHandler( xml.sax.ContentHandler

APIs. For a complete detail on SAX API documentation, please refer to the standard Python SAX

## Parsing XML with DOM APIs

The Document Object Model ("DOM") is a cross-language API from the World Wide Web Consortium (W3C) for accessing and modifying the XML documents.

of one bit of the document at a time. If you are looking at one SAX element, you have no access to another. The DOM is extremely useful for random-access applications. SAX only allows you a view

quickly creates a DOM tree from the XML file using the xml.dom module. The minidom object Here is the easiest way to load an XML document quickly and to create a minidom object provides മ simple parser method

The sample phrase calls the parse( file [,parser] ) function of the minidom object to parse XML file, designated by file into a DOM tree object.

```
if collection.hasAttribute("shelf"):
                                                                                                  collection = DOMTree.documentElement
                                                                                                                                             DOMTree = xml.dom.minidom.parse("movies.xml")
                                                                                                                                                                                                                                                                                                import xml.dom.minidom

# 27. Python 3 – GUI Programming (Tkinter)

important features are listed below. Python provides various options for developing graphical user interfaces (GUIs). The most

- Tkinter: Tkinter is the Python interface to the Tk GUI toolkit shipped with Python. We would look at this option in this chapter.
- wxPython: This is an open-source Python interface for wxWidgets GUI toolkit. You can find a complete tutorial on WxPython here
- TutorialsPoint has a very good tutorial on PyQt here. PyQt:This is also a Python interface for a popular cross-platform Qt GUI library.
- access to the Java class libraries on the local machine<u>http://www.jython.org</u>. JPython: JPython is a Python port for Java, which gives Python scripts seamless

There are many other interfaces available, which you can find them on the net

## Tkinter Programming

interface to the Tk GUI toolkit. a fast and easy way to create GUI applications. Tkinter provides a powerful object-oriented Tkinter is the standard GUI library for Python. Python when combined with Tkinter provides

following steps Creating a GUI application using Tkinter is an easy task. All you need to do is perform the

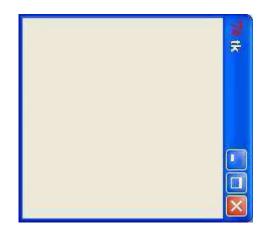

- Import the Tkinter module
- Create the GUI application main window.
- Add one or more of the above-mentioned widgets to the GUI application.
- Enter the main event loop to take action against each event triggered by the user.

#### Example

```
#!/usr/bin/python3
                                          # Code to add widgets will go here...
                                                                                        top = tkinter.Tk()
                                                                                                                                    Python
top.mainloop()
                                                                                                                                                               import tkinter # note that module name has changed from Tkinter in Python 2
                                                                                                                                                                    to tkinter in
```

This would create a following window-

#### **Tkinter Widgets**

Tkinter provides various controls, such as buttons, labels and text boxes used in a GUI application. These controls are commonly called widgets.

There are currently 15 types of widgets in Tkinter. We present these widgets as well as a brief description in the following table-  ${\sf T}$ 

Operator	Description
Button	The Button widget is used to display the buttons in your application.
Canvas	The Canvas widget is used to draw shapes, such as lines, ovals, polygons and rectangles, in your application.
Checkbutton	The Checkbutton widget is used to display a number of options as checkboxes. The user can select multiple options at a time.
Entry	The Entry widget is used to display a single-line text field for accepting values from a user.
Frame	The Frame widget is used as a container widget to organize other widgets.
Label	The Label widget is used to provide a single-line caption for other widgets. It can also contain images.

This module is used to display the message boxes in your applications.	tkMessageBox
A labelframe is a simple container widget. Its primary purpose is to act as a spacer or container for complex window layouts.	LabelFrame
A PanedWindow is a container widget that may contain any number of panes, arranged horizontally or vertically.	PanedWindow
The Spinbox widget is a variant of the standard Tkinter Entry widget, which can be used to select from a fixed number of values.	Spinbox
The Toplevel widget is used to provide a separate window container.	Toplevel
The Text widget is used to display text in multiple lines.	Text
The Scrollbar widget is used to add scrolling capability to various widgets, such as list boxes.	Scrollbar
The Scale widget is used to provide a slider widget.	Scale
The Radiobutton widget is used to display a number of options as radio buttons. The user can select only one option at a time.	Radiobutton
The Message widget is used to display multiline text fields for accepting values from a user.	Message
The Menu widget is used to provide various commands to a user. These commands are contained inside Menubutton.	Menu
The Menubutton widget is used to display menus in your application.	Menubutton
The Listbox widget is used to provide a list of options to a user.	Listbox

Let us study these widgets in detail.

#### **Tkinter Button**

The Button widget is used to add buttons in a Python application. These buttons can display text or images that convey the purpose of the buttons. You can attach a function or a method to a button which is called automatically when you click the button.

#### Syntax

Here is the simple syntax to create this widget-

```
П
Button ( master, option=value,
:
```

#### **Parameters**

- master: This represents the parent window.
- options can be used as key-value pairs separated by commas. options: Here is the list of most commonly used options for this widget. These

Normal background color.	bd Bor
Background color when the button is under the cursor.  Foreground color when the button is under the cursor.	<b>Option</b> activebackground  Bac  activeforeground  For

wrapped to fit within this length.	
If this value is set to a positive number, the text lines will be	wraplength
Width of the button in letters (if displaying text) or pixels (if	width
character will be underlined.	
Default is -1, meaning that no character of the text on the button will be underlined. If nonnegative, the corresponding text	underline
Default is NORMAL.	
Set this option to DISABLED to gray out the button and make it unresponsive. Has the value ACTIVE when the mouse is over it.	state
טפואירוא, ואסנטרט, פואסטיר, מוש הנדטטר.	
Relief specifies the type of the border. Some of the values are	relief
	3
Additional padding above and below the text	nadv
Additional padding left and right of the text.	padx
How to show multiple text lines: LEFT to left-justify each line; CENTER to center them: or RIGHT to right-justify.	justify
יייים אר מיישומ <i>וור ממרימוי</i> (יייפירמת מי נכאר).	1000
Tennen to be displayed as the britten (instead of text)	
The color of the focus highlight when the widget has focus.	highlightcolor

#### **Methods**

Following are commonly used methods for this widget-

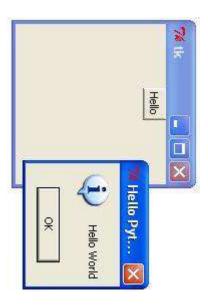

the button is disabled.

Try the following example yourself-

```
B.place(x=50, y=50)
                                                                                                                                                           def helloCallBack():
                                                                                                                                                                                           top.geometry("100x100")
                                                                                                                                                                                                                                                                                                                                                          # !/usr/bin/python3
top.mainloop()
                                                                                                                                                                                                                                       top = Tk()
                                                                                                                                                                                                                                                                              from tkinter import messagebox
                                                                                                                                                                                                                                                                                                                    from tkinter import
                                                                                                                 msg=messagebox.showinfo( "Hello Python", "Hello World")
                                                                          Button(top, text ="Hello", command = helloCallBack)
```

When the above code is executed, it produces the following result-

# **Tkinter Canvas**

The Canvas is a rectangular area intended for drawing pictures or other complex layouts. You can place graphics, text, widgets or frames on a Canvas.

#### Syntax

Here is the simple syntax to create this widget-

```
П
 Canvas
master,
option=value,
```

- master: This represents the parent window.
- options: Here is the list of most commonly used options for this widget. These options can be used as key-value pairs separated by commas.

Option	Description
bd	Border width in pixels. Default is 2.
bg	Normal background color.
confine	If true (the default), the canvas cannot be scrolled outside of the scrollregion.
cursor	Cursor used in the canvas like arrow, circle, dot etc.
height	Size of the canvas in the Y dimension.
highlightcolor	Color shown in the focus highlight.
relief	Relief specifies the type of the border. Some of the values are SUNKEN, RAISED, GROOVE, and RIDGE.
scrollregion	A tuple (w, n, e, s) that defines over how large an area the canvas can be scrolled, where w is the left side, n the top, e the right side, and s the bottom.
width	Size of the canvas in the X dimension.
xscrollincrement	If you set this option to some positive dimension, the canvas can be positioned only on multiples of that distance, and the value will be used for scrolling by scrolling units, such as when the user clicks on the arrows at the ends of a scrollbar.
xscrollcommand	If the canvas is scrollable, this attribute should be the .set() method of the horizontal scrollbar.
yscrollincrement	Works like xscrollincrement, but governs vertical movement.
yscrollcommand	If the canvas is scrollable, this attribute should be the .set() method of the vertical scrollbar.

The Canvas widget can support the following standard items-

arc . Creates an arc item, which can be a chord, a pieslice or a simple arc.

coord = 10, 50, 240, 210

```
arc
    П
 canvas.create_arc(coord,
  start=0,
extent=150, fill="blue")
```

image . Creates an image item, which can be an instance of either the BitmapImage the PhotoImage classes. 윽

```
filename = PhotoImage(file
= canvas.create_image(50,
                         = "sunshine.gif")
  50,
  anchor=NE,
  image=filename)
```

line. Creates a line item.

```
line
canvas.create_line(x0, y0,
×1,
у1,
::
xn,
yn,
options)
```

**oval** . Creates a circle or an ellipse at the given coordinates. It takes two pairs of coordinates; the top left and bottom right corners of the bounding rectangle for the oval. circle 약

```
canvas.create_oval(x0, y0, x1, y1, options)
```

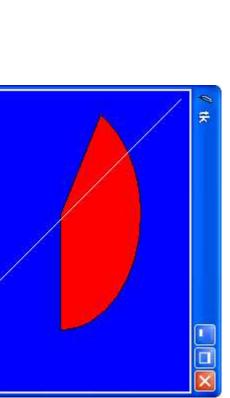

**polygon**. Creates a polygon item that must have at least three vertices

```
oval
canvas.create_polygon(x0,
 ²
Ø
×1,
y1,...xn,
 'n
 options)
```

#### Example

```
top
                                                  line = C.create_line(10,10,200,200,fill='white')
                                                                                                                                                            \cap
                                                                                                                                                                                                                                                                                                                  from tkinter import *
                                                                                                                                                                                                                                                                                                                                             # !/usr/bin/python3
Top.mainloop()
                            C.pack()
                                                                                                        coord = 10,
                                                                                                                                                                                                                                                                from tkinter import messagebox
                                                                                П
                                                                                                                                                          Canvas(top, bg="blue", height=250, width=300)
                                                                              C.create_arc(coord,
                                                                                                                                                                                                              Tk()
                                                                                                      50,
                                                                                                      240,
                                                                                                          210
                                                                           start=0, extent=150, fill="red")
```

# Tkinter Checkbutton

The Checkbutton widget is used to display a number of options to a user as toggle buttons. The user can then select one or more options by clicking the button corresponding to each

You can also display images in place of text.

#### **Syntax**

Here is the simple syntax to create this widget-

```
w = Checkbutton ( master, option, ... )
```

- master: This represents the parent window.
- **options:** Here is the list of most commonly used options for this widget. These options can be used as key-value pairs separated by commas.

Option	Description
activebackground	Background color when the checkbutton is under the cursor.

The font used for the text.	The color used to render the text.	number of lines of text on the checkbutton. D	e number of lines of text on the checkbutton. Descriptions of the focus highlight when the checkus.	e number of lines of text on the checkbutton. De color of the focus highlight when the check us.  display a graphic image on the button.	umber of lines of text on the checkbutton olor of the focus highlight when the cheplay a graphic image on the button.  text contains multiple lines, this option text contains multiple lines, this option text contains multiple lines, this option	The number of lines of text on the checkbutton. Default is 1. The color of the focus highlight when the checkbutton has focus.  To display a graphic image on the button.  If the text contains multiple lines, this option controls how text is justified: CENTER, LEFT, or RIGHT.  Normally, a checkbutton's associated control variable will be to 0 when it is cleared (off). You can supply an alternate value the off state by setting offvalue to that value.
	text.		ight when the checkbutton has t	ight when the checkbutton has t		heckbutton has on controls how variable will be alternate value
ť			color of the focus highlight when the checkbutton has thus.	color of the focus highlight when the checkbutton has thus.  Jisham a graphic image on the button.	olor of the focus highlight when the cheplay a graphic image on the button.  text contains multiple lines, this option is justified: CENTER, LEFT, or RIGHT.	The color of the focus highlight when the checkbutton has the focus.  To display a graphic image on the button.  If the text contains multiple lines, this option controls how the text is justified: CENTER, LEFT, or RIGHT.  Normally, a checkbutton's associated control variable will be set to 0 when it is cleared (off). You can supply an alternate value for the off state by setting offvalue to that value.

Normally, lines are not wrapped. You can set this option to a number of characters and all lines will be broken into pieces no longer than that number.	wraplength
The default width of a checkbutton is determined by the size of the displayed image or text. You can set this option to a number of characters and the checkbutton will always have room for that many characters.	width
The control variable that tracks the current state of the checkbutton. Normally this variable is an <i>IntVar</i> , and 0 means cleared and 1 means set, but see the offvalue and onvalue options above.	variable
With the default value of -1, none of the characters of the text label are underlined. Set this option to the index of a character in the text (counting from zero) to underline that character.	underline
The label displayed next to the checkbutton. Use newlines ("\n") to display multiple lines of text.	text
The default is state=NORMAL, but you can use state=DISABLED to gray out the control and make it unresponsive. If the cursor is currently over the checkbutton, the state is ACTIVE.	state
If you set this option to an image, that image will appear in the checkbutton when it is set.	selectimage
The color of the checkbutton when it is set. Default selectcolor="red".	selectcolor
With the default value, relief=FLAT, the checkbutton does not stand out from its background. You may set this option to any of the other styles	relief
How much space to leave above and below the checkbutton and text. Default is 1 pixel.	pady
How much space to leave to the left and right of the checkbutton and text. Default is 1 pixel.	padx

Following are commonly used methods for this widget-

Method	Description
deselect()	Clears (turns off) the checkbutton.
flash()	Flashes the checkbutton a few times between its active and normal colors, but leaves it the way it started.
invoke()	You can call this method to get the same actions that would occur if the user clicked on the checkbutton to change its state.
select()	Sets (turns on) the checkbutton.
toggle()	Clears the checkbutton if set, sets it if cleared.

```
C2.pack()
                                                          C1.pack()
                                                                                                                                                                                                                                     C1 = Checkbutton(top, text = "Music", variable = CheckVar1, \
                                                                                                                                                                                                                                                                   CheckVar2 = IntVar()
                                                                                                                                                                                                                                                                                                 CheckVar1 =
                                                                                                                                                                                                                                                                                                                              top = Tk()
                                                                                                                                                                                                                                                                                                                                                                                       import tkinter
                                                                                                                                                                                                                                                                                                                                                                                                                                                 from tkinter import *
top.mainloop()
                                                                                                                                                      ^{\circ}
                                                                                                                                                                                                                                                                                                                                                                                                                                                                             !/usr/bin/python3
                                                                                                                                                Checkbutton(top, text = "Video", variable = CheckVar2, \
                                                                                                                                                                                                                                                                                                IntVar()
                                                                                                                                                                             width = 20,
                                                                                        width = 20)
                                                                                                                   onvalue = 1, offvalue = 0, height=5, \
                                                                                                                                                                                                        onvalue = 1, offvalue = 0, height=5,
```

# Tkinter Entry

The Entry widget is used to accept single-line text strings from a user.

- the Text widget. If you want to display multiple lines of text that can be edited, then you should use
- If you want to display one or more lines of text that cannot be modified by the user, then you should use the Label widget.

#### Syntax

Here is the simple syntax to create this widget-

```
Entry( master,
option,
:
\overline{\phantom{a}}
```

- master: This represents the parent window.
- options can be used as key-value pairs separated by commas. options: Here is the list of most commonly used options for this widget. These

command	A procedure to be called every time the user changes the state of this checkbutton.
cursor	If you set this option to a cursor name (arrow, dot etc.), the mouse cursor will change to that pattern when it is over the checkbutton.
font	The font used for the text.
exportselection	By default, if you select text within an Entry widget, it is automatically exported to the clipboard. To avoid this exportation, use exportselection=0.
- 6j	The color used to render the text.
highlightcolor	The color of the focus highlight when the checkbutton has the focus.
justify	If the text contains multiple lines, this option controls how the text is justified: CENTER, LEFT, or RIGHT.
relief	With the default value, relief=FLAT, the checkbutton does not stand out from its background. You may set this option to any of the other styles
selectbackground	The background color to use displaying selected text.
selectborderwidth	The width of the border to use around selected text. The default is one pixel.
selectforeground	The foreground (text) color of selected text.
woys	Normally, the characters that the user types appear in the entry. To make a .password. entry that echoes each character as an asterisk, set show="*".
state	The default is state=NORMAL, but you can use state=DISABLED to gray out the control and make it unresponsive. If the cursor is currently over the checkbutton, the state is ACTIVE.
textvariable	In order to be able to retrieve the current text from your entry widget, you must set this option to an instance of the StringVar class.

If you expect that users will often enter more text than the onscreen size of the widget, you can link your entry widget to a scrollbar.	xscrollcommand
The default width of a checkbutton is determined by the size of the displayed image or text. You can set this option to a number of characters and the checkbutton will always have room for that many characters.	width

Following are commonly used methods for this widget-

Method	Description
delete ( first, last=None )	Deletes characters from the widget, starting with the one at index first, up to but not including the character at position last. If the second argument is omitted, only the single character at position first is deleted.
get()	Returns the entry's current text as a string.
icursor ( index )	Set the insertion cursor just before the character at the given index.
index ( index )	Shift the contents of the entry so that the character at the given index is the leftmost visible character. Has no effect if the text fits entirely within the entry.
insert ( index, s )	Inserts string s before the character at the given index.
select_adjust ( index )	This method is used to make sure that the selection includes the character at the specified index.
select_clear()	Clears the selection. If there isn't currently a selection, has no effect.

Used to scroll the entry horizontally. The what argument must be either UNITS, to scroll by character widths, or PAGES, to scroll by chunks the size of the entry widget. The number is positive to scroll left to right, negative to scroll right to left.	xview_scroll ( number, what )
This method is useful in linking the Entry widget to a horizontal scrollbar.	xview ( index )
Selects all the text from the ANCHOR position up to but not including the character at the given index.	select_to ( index )
Sets the selection under program control. Selects the text starting at the start index, up to but not including the character at the end index. The start position must be before the end position.	select_range ( start, end )
If there is a selection, returns true, else returns false.	select_present()
Sets the ANCHOR index position to the character selected by index, and selects that character.	select_from ( index )

```
top.mainloop()
                                                     E1.pack(side = RIGHT)
                                                                               E1 = Entry(top, bd = 5)
                                                                                                          L1.pack( side = LEFT)
                                                                                                                                    L1 = Label(top, text="User Name")
                                                                                                                                                                top = Tk()
                                                                                                                                                                                                                     from tkinter import *
                                                                                                                                                                                                                                               # !/usr/bin/python3

# **Tkinter Frame**

arranging the position of other widgets. widgets in a somehow friendly way. The Frame widget is very important for the It works like a container, which is responsible for process of grouping and organizing other

widgets. these widgets. A frame can also be used as a foundation class to implement complex It uses rectangular areas in the screen to organize the layout and to provide padding of

#### Syntax

Here is the simple syntax to create this widget-

```
٤
Ш
Frame
master,
option,
```

- master: This represents the parent window.
- options can be used as key-value pairs separated by commas. options: Here is the list of most commonly used options for this widget. These

Options	Description
bg	The normal background color displayed behind the label and indicator.
bd	The size of the border around the indicator. Default is 2 pixels.
cursor	If you set this option to a cursor name (arrow, dot etc.), the mouse cursor will change to that pattern when it is over the checkbutton.
height	The vertical dimension of the new frame.
highlightbackground	Color of the focus highlight when the frame does not have focus.
highlightcolor	Color shown in the focus highlight when the frame has the focus.

width T	relief V	highlightthickness
The default width of a checkbutton is determined by the size of the displayed image or text. You can set this option to a number of characters and the checkbutton will always have room for that many characters.	With the default value, relief=FLAT, the checkbutton does not stand out from its background. You may set this option to any of the other styles	Thickness of the focus highlight.

```
bluebutton.pack( side = LEFT )
                                                                                                                                                                                                                                       bluebutton = Button(frame, text="Blue", fg="blue")
                                                                                                                                                                                                                                                                                                                    greenbutton.pack( side = LEFT )
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                               bottomframe.pack( side = BOTTOM )

                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      bottomframe = Frame(root)
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                 = Tk()
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                         = Frame(root)
```

# Tkinter Label

This widget implements a display box where you can place text or images. displayed by this widget can be updated at any time you want. The text

It is also possible to underline part of the text (like to identify a keyboard shortcut) and span the text across multiple lines.

#### Syntax

Here is the simple syntax to create this widget-

```
Σ
Label ( master,
option,
:
```

- master: This represents the parent window.
- options can be used as key-value pairs separated by commas. options: Here is the list of most commonly used options for this widget. These

Options	Description
anchor	This options controls where the text is positioned if the widget has more space than the text needs. The default is anchor=CENTER, which centers the text in the available space.
bg	The normal background color displayed behind the label and indicator.
bitmap	Set this option equal to a bitmap or image object and the label will display that graphic.
bd	The size of the border around the indicator. Default is 2 pixels.
cursor	If you set this option to a cursor name (arrow, dot etc.), the mouse cursor will change to that pattern when it is over the checkbutton.
font	If you are displaying text in this label (with the text or textvariable option, the font option specifies in what font that text will be displayed.

You can limit the number of characters in each line by setting this option to the desired number. The default value, 0, means that lines will be broken only at newlines.	wraplength
Width of the label in characters (not pixels!). If this option is not set, the label will be sized to fit its contents.	width
You can display an underline (_) below the nth letter of the text, counting from 0, by setting this option to n. The default is underline=-1, which means no underlining.	underline
To slave the text displayed in a label widget to a control variable of class StringVar, set this option to that variable.	textvariable
To display one or more lines of text in a label widget, set this option to a string containing the text. Internal newlines ("\n") will force a line break.	text
Specifies the appearance of a decorative border around the label. The default is FLAT; for other values.	relief
Extra space added above and below the text within the widget. Default is 1.	pady
Extra space added to the left and right of the text within the widget. Default is 1.	padx
Specifies how multiple lines of text will be aligned with respect to each other: LEFT for flush left, CENTER for centered (the default), or RIGHT for right-justified.	justify
To display a static image in the label widget, set this option to an image object.	image
The vertical dimension of the new frame.	height
If you are displaying text or a bitmap in this label, this option specifies the color of the text. If you are displaying a bitmap, this is the color that will appear at the position of the 1-bits in the bitmap.	fg

Try the following example yourself-

```
root
                                                                                                                                                                                                                                                                 # !/usr/bin/python3
root.mainloop()
                                                    var.set("Hey!? How are you doing?")
                           label.pack()
                                                                                                        label = Label( root,
                                                                                                                                   var =
                                                                                                                                                                                                                                         from tkinter import *
                                                                                                                                                                                    = Tk()
                                                                                                                               StringVar()
                                                                                                      textvariable=var, relief=RAISED )
```

When the above code is executed, it produces the following result-

# Tkinter Listbox

The Listbox widget is used to display a list of items from which a user can select a number of items

#### Syntax

Here is the simple syntax to create this widget-

```
٤
    П
Listbox ( master, option, ... )
```

- master: This represents the parent window.
- **options:** Here is the list of most commonly used options for this widget. These options can be used as key-value pairs separated by commas.

Options	Description
ба	The normal background color displayed behind the label and indicator.

width The width of the widget in characters.	lines to th	• MUL once selec	• SIN drag	• BRO of a diffe is th	selectmode Determines	selectbackground The backgro	relief Selects thre is SUNKEN.	highlightthickness o	highlightcolor Color shown focus.	height Number of 10.	fg The color us		font The font us	or	Or	The color us  Number of I 10.  Color shown focus.  Thickness o Selects thre is SUNKEN.  The background drags affect  BRO of a diffe is the drags is selected once selected to the toth once selected to
	<b>EXTENDED:</b> You can select any adjacent group of lines at once by clicking on the first line and dragging to the last line.	<b>MULTIPLE:</b> You can select any number of lines at once. Clicking on any line toggles whether or not it is selected.	<b>SINGLE:</b> You can only select one line, and you can't drag the mouse.wherever you click button 1, that line is selected.	<b>BROWSE:</b> Normally, you can only select one line out of a listbox. If you click on an item and then drag to a different line, the selection will follow the mouse. This is the default.	Determines how many items can be selected, and how mouse drags affect the selection:	The background color to use displaying selected text.	Selects three-dimensional border shading effects. The default is SUNKEN.	Thickness of the focus highlight.	Color shown in the focus highlight when the widget has the focus.	Number of lines (not pixels!) shown in the listbox. Default is 10.	The color used for the text in the listbox.	The font used for the text in the listbox.		The cursor that appears when the mouse is over the listbox.	of the border around the indicator. Default is 2 or that appears when the mouse is over the listbox.	in the listbox.  t in the listbox.  s!) shown in the listbox. Default s!) shown in the listbox. Default highlight when the widget has the highlight when the widget has the highlight when the widget has the light.  border shading effects. The defallow can be selected, and how mount it election will follow the mouse. The line of lines and select any number of lines and select any adjacent group cking on the first line and dragging in the line a

yscrollcommand	xscrollcommand
If you want to allow the user to scroll the listbox vertically, you can link your listbox widget to a vertical scrollbar.	If you want to allow the user to scroll the listbox horizontally, you can link your listbox widget to a horizontal scrollbar.

Methods on listbox objects include-

Options Descri	activate ( index )  Selects the line specifies by	curselection()  Returns a tuple containing selected element or element or element or element or eturns	delete ( first, last=None )  Deletes the lines whose individual last]. If the second argumer with index first is deleted.	get ( first, last=None ) Returns a tuple containing indices from first to last, argument is omitted, returns to first.	index ( i )  If possible, positions the virthat the line containing index widget.	insert ( index, *elements )  Insert one or more new lines line specified by index. Use if you want to add new lines		nearest ( y )  Return the index of the visible line coordinate y relative to the listbox wi	
Description	Selects the line specifies by the given index.	<u></u>	Deletes the lines whose indices are in the range [first, last]. If the second argument is omitted, the single line with index first is deleted.	Returns a tuple containing the text of the lines with indices from first to last, inclusive. If the second argument is omitted, returns the text of the line closest to first.	If possible, positions the visible part of the listbox so that the line containing index i is at the top of the widget.	Insert one or more new lines into the listbox before the line specified by index. Use END as the first argument if you want to add new lines to the end of the listbox.	.he index of the visible line closest to the v-	coordinate y relative to the listbox widget.	te y relative to the listbox widget.  The position of the listbox so that the to by index is visible.

Scrolls the listbox vertically. For the what argument, use either UNITS to scroll by lines, or PAGES to scroll by pages, that is, by the height of the listbox. The number argument tells how many to scroll.	yview_scroll ( number, what )
Scroll the listbox so that the top fraction of the width of its longest line is outside the left side of the listbox. Fraction is in the range [0,1].	yview_moveto ( fraction )
To make the listbox vertically scrollable, set the command option of the associated vertical scrollbar to this method.	yview()
Scrolls the listbox horizontally. For the what argument, use either UNITS to scroll by characters, or PAGES to scroll by pages, that is, by the width of the listbox. The number argument tells how many to scroll.	xview_scroll ( number, what )
Scroll the listbox so that the leftmost fraction of the width of its longest line is outside the left side of the listbox. Fraction is in the range [0,1].	xview_moveto ( fraction )
To make the listbox horizontally scrollable, set the command option of the associated horizontal scrollbar to this method.	xview()

```
Lb1.insert(4, "PHP")
                       Lb1.insert(3, "C")
                                             Lb1.insert(2, "Perl")
                                                                   Lb1.insert(1, "Python")
                                                                                           Lb1 = Listbox(top)
                                                                                                                                        top = Tk()
                                                                                                                                                                                    import tkinter
                                                                                                                                                                                                                                from tkinter import *
                                                                                                                                                                                                                                                      # !/usr/bin/python3
```

```
Lb1.pack()
                                                 Lb1.insert(6, "Ruby")
                                                                   Lb1.insert(5,
top.mainloop()
                                                                     "JSP")
```

# **Tkinter Menubutton**

A menubutton is the part of a drop-down menu that stays on the screen all the time. Every menubutton is associated with a Menu widget that can display the choices for that menubutton when the user clicks on it.

#### Syntax

Here is the simple syntax to create this widget-

```
٤
Menubutton
( master,
option,
```

- master: This represents the parent window.
- **options:** Here is the list of most commonly used options for this widget. These options can be used as key-value pairs separated by commas.

The foreground color when the mouse is over the menubutton.	activeforeground
The background color when the mouse is over the menubutton.	activebackground
Description	Options

text (this is the default); use justify=CENTER to center it, or justify=RIGHT to right-justify.  To associate the menubutton with a set of choices, set this option to the Menu object containing those choices. That menu object must have been created by passing the associated menubutton to the constructor as its first argument.
To display an image on this menubutton,  This option controls where the text is located when the text doesn't fill the menubutton: use justify=LEFT to left-justify the
Color shown in the focus highlight when the widget has the focus.
The height of the menubutton in lines of text (not pixels!). The default is to fit the menubutton's size to its contents.
The foreground color when the menubutton.
The foreground color shown on disabled.
Set direction=LEFT to display the menu to the left of the button; use direction=RIGHT to display the menu to the right of the button; or use direction='above' to place the menu above the button.
The cursor that appears when the mouse is over this menubutton.
The size of the border around the indicator.
To display a bitmap on the menubutton, set this bitmap name.
The normal background color displayed indicator.
This options controls where the text is positioned if the widget has more space than the text needs. The default is anchor=CENTER, which centers the text.

wraplength   N	width T	underline N t	textvariable Y n c	text T	state N	relief S	pady H	padx H
Normally, lines are not wrapped. You can set this option to a number of characters and all lines will be broken into pieces no longer than that number.	The width of the widget in characters. The default is 20.	Normally, no underline appears under the text on the menubutton. To underline one of the characters, set this option to the index of that character.	You can associate a control variable of class StringVar with this menubutton. Setting that control variable will change the displayed text.	To display text on the menubutton, set this option to the string containing the desired text. Newlines ("\n") within the string will cause line breaks.	Normally, menubuttons respond to the mouse. Set state=DISABLED to gray out the menubutton and make it unresponsive.	Selects three-dimensional border shading effects. The default is RAISED.	How much space to leave above and below the text of the menubutton. Default is 1.	How much space to leave to the left and right of the text of the menubutton. Default is 1.

```
mb=
                                           top = Tk()
                                                                                      import tkinter
                                                                                                                                  from tkinter import *
                                                                                                                                                      # !/usr/bin/python3
Menubutton ( top, text="condiments",

# **Tkinter Menu**

toplevel and pull-down. applications. The core functionality provides ways to create three menu types: pop-up, The goal of this widget is to allow us to create all kinds of menus that can be used by our

as the OptionMenu widget, which implements a special type that generates a pop-up list It is also possible to use other extended widgets to implement new types of menus, such of items within a selection.

#### Syntax

Here is the simple syntax to create this widget-

```
٤
  П
Menu ( master,
option,
```

## **Parameters**

master: This represents the parent window.

**options:** Here is the list of most commonly used options for this widget. These options can be used as key-value pairs separated by commas.

selectcolor Specifies the color dispersion when they are selected	To display an im	relief The default 3-D	postcommand You can set this option to a called every time someone	fg The foreground	font The default font	disabledforeground The color of the	cursor  The cursor that appears when only when the menu has been	bd The width of the	bg The background	activeforeground the mouse.	activeborderwidth Specifies the wider the mouse	activebackground The background the mouse.	Options
The foreground color used for choices not under the mouse.  You can set this option to a procedure, and that procedure will be called every time someone brings up this menu.  The default 3-D effect for menus is relief=RAISED.  To display an image on this menubutton.  Specifies the color displayed in checkbuttons and radiobuttons when they are selected.			color used for choices not under the mouse.		default font for textual choices.	text for items whose state is DISABLED.	The cursor that appears when the mouse is over the choices, but only when the menu has been torn off.	e border around all the choices. Default is 1.	l color for choices not under the mouse.	The foreground color that will appear on a choice when it is under the mouse.	Specifies the width of a border drawn around a choice when it is under the mouse. Default is 1 pixel.	The background color that will appear on a choice when it is under the mouse.	Description

Normally, the title of a tear-off menu window will be the same as the text of the menubutton or cascade that lead to this menu. If you want to change the title of that window, set the title option to that string.	title
tearoff=0, the menu will not have a tear-off feature, and choices will be added starting at position 0.	

These methods are available on Menu objects-

Option	Description
add_command (options)	Adds a menu item to the menu.
add_radiobutton( options )	Creates a radio button menu item.
add_checkbutton( options )	Creates a check button menu item.
add_cascade(options)	Creates a new hierarchical menu by associating a given menu to a parent menu
add_separator()	Adds a separator line to the menu.
add( type, options )	Adds a specific type of menu item to the menu.
delete( startindex [, endindex ])	Deletes the menu items ranging from startindex to endindex.
entryconfig( index, options )	Allows you to modify a menu item, which is identified by the index, and change its options.
index(item)	Returns the index number of the given menu item label.
insert_separator ( index )	Insert a new separator at the position specified by index.

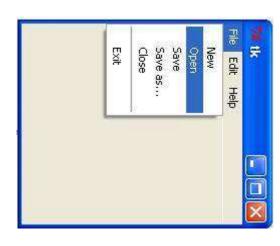

type ( index )	invoke ( index )
Returns the type of the choice specified by index: either "cascade", "checkbutton", "command", "radiobutton", "separator", or "tearoff".	Calls the command callback associated with the choice at position index. If a checkbutton, its state is toggled between set and cleared; if a radiobutton, that choice is set.

```
editmenu.add_command(label="Undo", command=donothing)
                                                  editmenu = Menu(menubar, tearoff=0)
                                                                                                      menubar.add_cascade(label="File", menu=filemenu)
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  menubar = Menu(root)
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          def donothing():

                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                           editmenu.add_separator()
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             command=donothing)
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        command=donothing)
```

# Tkinter Message

breaking lines and justifying their contents. This widget provides a multiline and noneditable object that displays texts, automatically

also automatically wrap the text, maintaining a given width or aspect ratio. Its functionality is very similar to the one provided by the Label widget, except that it can

#### Syntax

Here is the simple syntax to create this widget-

```
∑
II
Message ( master, option, ... )
```

- master: This represents the parent window.
- **options:** Here is the list of most commonly used options for this widget. These options can be used as key-value pairs separated by commas.

wraplength	width	underline	textvariable	text	relief	pady	padx
You can limit the number of characters in each line by setting this option to the desired number. The default value, 0, means that lines will be broken only at newlines.	Width of the label in characters (not pixels!). If this option is not set, the label will be sized to fit its contents.	You can display an underline (_) below the nth letter of the text, counting from 0, by setting this option to n. The default is underline=-1, which means no underlining.	To slave the text displayed in a label widget to a control variable of class <i>StringVar</i> , set this option to that variable.	To display one or more lines of text in a label widget, set this option to a string containing the text. Internal newlines ("\n") will force a line break.	Specifies the appearance of a decorative border around the label. The default is FLAT; for other values.	Extra space added above and below the text within the widget. Default is 1. $$	Extra space added to the left and right of the text within the widget. Default is 1. $ \label{eq:continuous} % \begin{center}$

```
label.pack()
                            var.set("Hey!? How are you doing?")
                                                                                            label = Message( root, textvariable=var, relief=RAISED )
                                                                                                                            var = StringVar()
                                                                                                                                                                                          root = Tk()
                                                                                                                                                                                                                                                        from tkinter import *
                                                                                                                                                                                                                                                                                       # !/usr/bin/python3
```

```
root.mainloop()
```

# Tkinter Radiobutton

This widget implements a multiple-choice button, which is a way to offer many possible selections to the user and lets user choose only one of them.

In order to implement this functionality, each group of radiobuttons must be associated to the same variable and each one of the buttons must symbolize a single value. You can use the Tab key to switch from one radionbutton to another.

#### Syntax

Here is the simple syntax to create this widget-

```
Radiobutton ( master,
option,
:
```

- master: This represents the parent window.
- options can be used as key-value pairs separated by commas. options: Here is the list of most commonly used options for this widget. These

Options	Description
activebackground	The background color when the mouse is over the radiobutton.
activeforeground	The foreground color when the mouse is over the radiobutton.
anchor	If the widget inhabits a space larger than it needs, this option specifies where the radiobutton will sit in that space. The default is anchor=CENTER.
bg	The normal background color behind the indicator and label.

You can limit the number of characters in each line by setting this option to the desired number. The default value, 0, means that lines will be broken only at newlines.	wraplength
Width of the label in characters (not pixels!). If this option is not set, the label will be sized to fit its contents.	width
The control variable that this radiobutton shares with the other radiobuttons in the group. This can be either an IntVar or a StringVar.	variable
When a radiobutton is turned on by the user, its control variable is set to its current value option. If the control variable is an <i>IntVar</i> , give each radiobutton in the group a different integer value option. If the control variable is a <i>StringVar</i> , give each radiobutton a different string value option.	value
You can display an underline (_) below the nth letter of the text, counting from 0, by setting this option to n. The default is underline=-1, which means no underlining.	underline
To slave the text displayed in a label widget to a control variable of class <i>StringVar</i> , set this option to that variable.	textvariable
The label displayed next to the radiobutton. Use newlines ("\n") to display multiple lines of text.	text
The default is state=NORMAL, but you can set state=DISABLED to gray out the control and make it unresponsive. If the cursor is currently over the radiobutton, the state is ACTIVE.	state
If you are using the image option to display a graphic instead of text when the radiobutton is cleared, you can set the selectimage option to a different image that will be displayed when the radiobutton is set.	selectimage

These methods are available.

Methods	Description
deselect()	Clears (turns off) the radiobutton.

select()	invoke()	flash()
Sets (turns on) the radiobutton.	You can call this method to get the same actions that would occur if the user clicked on the radiobutton to change its state.	Flashes the radiobutton a few times between its active and normal colors, but leaves it the way it started.

```
root.mainloop()
                                                                                                                                                                                                                                                                                                                                                                                                                               R1 = Radiobutton(root, text="Option 1", variable=var, value=1,

                                                                                                                                                                                                                                                                             command=sel)
                                                                                                                                                                                                                                                                                                                                                                                                    command=sel)
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    + str(var.get())
```

# Tkinter Scale

specific scale. The Scale widget provides a graphical slider object that allows you to select values from a

#### Syntax

Here is the simple syntax to create this widget-

```
٤
  П
Scale ( master, option, ... )
```

- master: This represents the parent window.
- options can be used as key-value pairs separated by commas. options: Here is the list of most commonly used options for this widget. These

Options	Description
activebackground	The background color when the mouse is over the scale.
bg	The background color of the parts of the widget that are outside the trough.
bd	Width of the 3-d border around the trough and slider. Default is 2 pixels.
command	A procedure to be called every time the slider is moved. This procedure will be passed one argument, the new scale value. If the slider is moved rapidly, you may not get a callback for every possible position, but you'll certainly get a callback when it settles.

resolution	repeatdelay	relief	orient	length	label	highlightcolor	highlightbackground	from_	fg	font	digits	cursor
Normally, the user will only be able to change the scale in whole units. Set this option to some other value to change the smallest	This option controls how long button 1 has to be held down in the trough before the slider starts moving in that direction repeatedly. Default is repeatdelay=300, and the units are milliseconds.	Specifies the appearance of a decorative border around the label. The default is FLAT; for other values.	Set orient=HORIZONTAL if you want the scale to run along the x dimension, or orient=VERTICAL to run parallel to the y-axis. Default is horizontal.	The length of the scale widget. This is the $x$ dimension if the scale is horizontal, or the $y$ dimension if vertical. The default is 100 pixels.	You can display a label within the scale widget by setting this option to the label's text. The label appears in the top left corner if the scale is horizontal, or the top right corner if vertical. The default is no label.	The color of the focus highlight when the scale has the focus.	The color of the focus highlight when the scale does not have focus.	A float or integer value that defines one end of the scale's range.	The color of the text used for the label and annotations.	The font used for the label and annotations.	The way your program reads the current value shown in a scale widget is through a control variable. The control variable for a scale can be an IntVar, a DoubleVar (float), or a StringVar. If it is a string variable, the digits option controls how many digits to use when the numeric scale value is converted to a string.	If you set this option to a cursor name (arrow, dot etc.), the mouse cursor will change to that pattern when it is over the scale.

showvalue sliderlength stakefocus takefocus	increment of the scale's value. For example, if from_=-1.0 and to=1.0, and you set resolution=0.5, the scale will have 5 possible values: -1.0, -0.5, 0.0, +0.5, and +1.0.  Normally, the current value of the scale is displayed in text form by the slider (above it for horizontal scales, to the left for vertical scales). Set this option to 0 to suppress that label.  Normally the slider is 30 pixels along the length of the scale. You can change that length by setting the sliderlength option to your desired length.  Normally, scale widgets respond to mouse events, and when they have the focus, also keyboard events. Set state=DISABLED to make the widget unresponsive.  Normally, the focus will cycle through scale widgets. Set this option to 0 if you don't want this behavior.  To display periodic scale values, set this option to a number, and ticks will be displayed on multiples of that value. For example, if from_=0.0, to=1.0, and tickinterval=0.25, labels will be displayed along the scale at values 0.0, 0.25, 0.50, 0.75, and 1.00. These labels appear below the scale if horizontal, to its left if vertical. Default is 0, which suppresses display of ticks.
6	Normally, scale widgets respond to mouse they have the focus, also keyboard events. Se to make the widget unresponsive.  Normally, the focus will cycle through scale option to 0 if you don't want this behavior.
interval	To display periodic scale values, set this op and ticks will be displayed on multiples of example, if from_=0.0, to=1.0, and tickint will be displayed along the scale at values 0.0 and 1.00. These labels appear below the scale of the front of the suppressits left if vertical. Default is 0, which suppressits left if vertical.
to	A float or integer value that defines one end of the scale's range; the other end is defined by the from_ option, discussed above. The to value can be either greater than or less than the from_ value. For vertical scales, the to value defines the bottom of the scale; for horizontal scales, the right end.
troughcolor	The color of the trough.
variable	The control variable for this scale, if any. Control variables may be from class IntVar, DoubleVar (float), or StringVar. In the latter case, the numerical value will be converted to a string.
width	The width of the trough part of the widget. This is the x dimension for vertical scales and the y dimension if the scale has orient=HORIZONTAL. Default is 15 pixels.

Scale objects have these methods-

Methods	Description
get()	This method returns the current value of the scale.
set ( value )	Sets the scale's value.

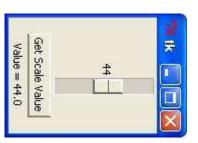

### Example

Try the following example yourself-

```
label.pack()
                                                                                                                                                                  button.pack(anchor=CENTER)
                                                                                                                                                                                                                                                                                                    scale = Scale( root, variable = var )
                                                                                                                                                                                                                                                                                                                                      var = DoubleVar()
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                         def sel():
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                           # !/usr/bin/python3
root.mainloop()
                                                                                                 label = Label(root)
                                                                                                                                                                                                   button = Button(root, text="Get Scale Value", command=sel)
                                                                                                                                                                                                                                                                    scale.pack(anchor=CENTER)
                                                                                                                                                                                                                                                                                                                                                                      root = Tk()
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            from tkinter import *
                                                                                                                                                                                                                                                                                                                                                                                                                                                                        selection = "Value = " + str(var.get())
                                                                                                                                                                                                                                                                                                                                                                                                                                     label.config(text = selection)
```

When the above code is executed, it produces the following result-

## **Tkinter Scrollbar**

This widget provides a slide controller that is used to implement vertical scrolled widgets, such as Listbox, Text and Canvas. Note that you can also create horizontal scrollbars on Entry widgets.

### Syntax

Here is the simple syntax to create this widget-

```
٤
   П
  Scrollbar
( master, option,
 \overline{\phantom{a}}
```

## **Parameters**

- master: This represents the parent window.
- **options:** Here is the list of most commonly used options for this widget. These options can be used as key-value pairs separated by commas.

Options	Description
activebackground	The color of the slider and arrowheads when the mouse is over them.
bg	The color of the slider and arrowheads when the mouse is not over them.
bd	The width of the 3-d borders around the entire perimeter of the trough, and also the width of the 3-d effects on the arrowheads and slider. Default is no border around the trough, and a 2-pixel border around the arrowheads and slider.
command	A procedure to be called whenever the scrollbar is moved.

cursor	
	The cursor that appears when the mouse is over the scrollbar.
elementborderwidth Th de va	The width of the borders around the arrowheads and slider. The default is elementborderwidth=-1, which means to use the value of the borderwidth option.
highlightbackground Th	The color of the focus highlight when the scrollbar does not have focus.
highlightcolor Th	The color of the focus highlight when the scrollbar has the focus.
highlightthickness The supp	The thickness of the focus highlight. Default is 1. Set to 0 to suppress display of the focus highlight.
Jump Th Nc co ca	This option controls what happens when a user drags the slider. Normally (jump=0), every small drag of the slider causes the command callback to be called. If you set this option to 1, the callback isn't called until the user releases the mouse button.
orient Set orie	Set orient=HORIZONTAL for a horizontal scrollbar, orient=VERTICAL for a vertical one.
repeatdelay This the repe	This option controls how long button 1 has to be held down in the trough before the slider starts moving in that direction repeatedly. Default is repeatdelay=300, and the units are milliseconds.
repeatinterval rep	repeatinterval
takefocus No tal	Normally, you can tab the focus through a scrollbar widget. Set takefocus=0 if you don't want this behavior.
troughcolor	The color of the trough.
width Wi	Width of the scrollbar (its y dimension if horizontal, and its $\times$ dimension if vertical). Default is 16.

## **Methods**

Scrollbar objects have these methods-

Methods
Description

set ( first, last ) To connect a scrollbar to another widget w, set w's xscrollcommand or yscrollcommand to the scrollbar's set() method. The arguments have the same meaning as the values returned by the get() method.	set ( first, last )
Returns two numbers (a, b) describing the current position of the slider. The a value gives the position of the left or top edge of the slider, for horizontal and vertical scrollbars respectively; the b value gives the position of the right or bottom edge.	get()

## Example

Try the following example yourself-

```
mylist =
                                                                                                                                                                         scrollbar.pack( side = RIGHT, fill=Y )
                                                                                                                                                                                                               root
mainloop()
                                     scrollbar.config( command = mylist.yview )
                                                        mylist.pack( side
                                                                                                                for line in range(100):
                                                                                                                                                                                                                                                    from tkinter import
                                                                                                                                                                                             scrollbar =
                                                                                                                                                                                                                                                                       !/usr/bin/python3
                                                                                             mylist.insert(END,
                                                                                                                                                                                                                П
                                                                                                                                                                                                                Tk()
                                                                                                                                   Listbox(root, yscrollcommand
                                                                                                                                                                                            Scrollbar(root)
                                                            П
                                                       LEFT,
                                                                                              "This
                                                          fill
                                                                                               is
                                                         = BOTH )
                                                                                              line number
                                                                                                                                       Ш
                                                                                                                                    scrollbar.set
                                                                                                   =
                                                                                                +
                                                                                             str(line))
```

When the above code is executed, it produces the following result-

## Tkinter Text

Text widgets provide advanced capabilities that allow you to edit a multiline format the way it has to be displayed, such as changing its color and font. text and

You can also use elegant structures like tabs and marks to locate specific sections of the text, and apply changes to those areas. Moreover, you can embed windows and images in the text because this widget was designed to handle both plain and formatted text.

### Syntax

Here is the simple syntax to create this widget-

```
Σ
  П
 Text
( master, option,
:
```

## **Parameters**

- master: This represents the parent window.
- options can be used as key-value pairs separated by commas. options: Here is the list of most commonly used options for this widget. These

Options	Description
бq	The default background color of the text widget.
bd	The width of the border around the text widget. Default is 2 pixels.
cursor	The cursor that will appear when the mouse is over the text widget.
exportselection	Normally, text selected within a text widget is exported to be the selection in the window manager. Set exportselection=0 if you don't want that behavior.
font	The default font for text inserted into the widget.
fg	The color used for text (and bitmaps) within the widget. You can change the color for tagged regions; this option is just the default.
height	The height of the widget in lines (not pixels!), measured according to the current font size.

This option specifies how much extra vertical space is put above each line of text. If a line wraps, this space is added only before the first line it occupies on the display. Default is 0.	spacing1
The width of the border to use around selected text.	selectborderwidth
The background color to use displaying selected text.	selectbackground
The 3-D appearance of the text widget. Default is relief=SUNKEN.	relief
The size of the internal padding added above and below the text area. Default is one pixel.	pady
The size of the internal padding added to the left and right of the text area. Default is one pixel.	padx
Width of the insertion cursor (its height is determined by the tallest item in its line). Default is 2 pixels.	insertwidth
The number of milliseconds the insertion cursor is on during its blink cycle. Default is 600.	insertontime
The number of milliseconds the insertion cursor is off during its blink cycle. Set this option to zero to suppress blinking. Default is 300.	insertofftime
Size of the 3-D border around the insertion cursor. Default is 0.	insertborderwidth
The color of the insertion cursor. Default is black.	insertbackground
The thickness of the focus highlight. Default is 1. Set highlightthickness=0 to suppress display of the focus highlight.	highlightthickness
The color of the focus highlight when the text widget has the focus.	highlightcolor
The color of the focus highlight when the text widget does not have focus.	highlightbackground

To make the text widget vertically scrollable, set this option to the set() method of the vertical scrollbar.	yscrollcommand
To make the text widget horizontally scrollable, set this option to the set() method of the horizontal scrollbar.	xscrollcommand
This option controls the display of lines that are too wide. Set wrap=WORD and it will break the line after the last word that will fit. With the default behavior, wrap=CHAR, any line that gets too long will be broken at any character.	wrap
The width of the widget in characters (not pixels!), measured according to the current font size.	width
This option controls how tab characters position text.	tabs
Normally, text widgets respond to keyboard and mouse events; set state=NORMAL to get this behavior. If you set state=DISABLED, the text widget will not respond, and you won't be able to modify its contents programmatically either.	state
This option specifies how much extra vertical space is added below each line of text. If a line wraps, this space is added only after the last line it occupies on the display. Default is 0.	spacing3
This option specifies how much extra vertical space to add between displayed lines of text when a logical line wraps. Default is 0.	spacing2

### **Methods**

Text objects have these methods-

	_		
	ľ	ζ	į
	7	ŧ	
ı	(	D	
ı	ſ	1	
í		3	
ı	C	5	
ı	č	5	
ı	,		
	U	מ	
۰	G	X	ì
i			
ľ	4	1	
	ζ	֡֡֡֡֡֡֡	
	ζ	7	,
	ζ	7	,
	てしいい	7	,
	ζ	7	,
	ζ	7	,
	ていいここ	しののでは	•
	てのいて	しののできる	
	てのいて	しののできる	
	ていいここ	しののできる	,

delete(startindex [,endindex])
This method deletes a specific character or a range of text.

get(startindex [,endindex])
This method returns a specific character or a range of text.

index(index)
Returns the absolute value of an index based on the given index.

## insert(index [,string]...)

This method inserts strings at the specified index location.

## see(index)

method returns true if the text located at the index position is visible

Text widgets support three distinct helper structures: Marks, Tabs, and Indexes-

have the following methods available when handling marks: Marks are used to bookmark positions between two characters within a given text. We

## **Methods & Description**

## index(mark)

Returns the line and column location of a specific mark.

## mark\_gravity(mark [,gravity])

gravity is set for the given mark. Returns the gravity of the given mark. If the second argument is provided, the

## mark\_names()

Returns all marks from the Text widget.

## mark\_set(mark, index)

Informs a new position to the given mark

## mark\_unset(mark)

Removes the given mark from the Text widget

modifying the display settings of specific text areas. Tags are also used to bind event callbacks to specific ranges of text. Tags are used to associate names to regions of text which makes easy the task 으

Following are the available methods for handling tabs-

## **Methods & Description**

## tag\_add(tagname, startindex[,endindex] ...)

positions startindex and endindex. This method tags either the position defined by startindex, or a range delimited by the

## tag\_config

property), and underline(used to underline the tagged text). You can use this method to configure the tag properties, which include, justify(center, left, or right), tabs(this property has the same functionality of the Text widget tabs's

tag\_delete(tagname)
This method is used to delete and remove a given tag.

## tag\_remove(tagname [,startindex[.endindex]] ...)

deleting the actual tag definition. After applying this method, the given tag is removed from the provided area without

### Example

Try the following example yourself-

```
root.mainloop()
                                                           text.tag_config("here",
                                                                                          text.tag_add("start", "1.8", "1.13")
                                                                                                                                                                                                                          text.insert(END, "Bye Bye....")
                                                                                                                                                                                                                                                         text.insert(INSERT, "Hello....")
                              text.tag_config("start", background="black", foreground="green")
                                                                                                                            text.tag_add("here",
                                                                                                                                                                                              text.pack()
                                                                                                                                                                                                                                                                                               text =
                                                                                                                                                                                                                                                                                                                             root =
                                                                                                                                                                                                                                                                                                                                                                                           from tkinter import *
                                                                                                                                                                                                                                                                                                                                                                                                                         !/usr/bin/python3
                                                                                                                                                                                                                                                                                                                            Tk()
                                                                                                                                                                                                                                                                                             Text(root)
                                                                                                                         "1.0",
                                                            background="yellow", foreground="blue")
```

When the above code is executed, it produces the following result-

## Tkinter Toplevel

Toplevel widgets work as windows that are directly managed by the window manager. They do not necessarily have a parent widget on top of them.

Your application can use any number of top-level windows

### Syntax

Here is the simple syntax to create this widget-

```
w = Toplevel
( option,
:
```

## **Parameters**

**options:** Here is the list of most commonly used options for this widget. These options can be used as key-value pairs separated by commas.

### **Methods**

Toplevel objects have these methods-

Displays the window, after using either the iconify or the withdraw methods

### frame()

Returns a system-specific window identifier.

## group(window)

Adds the window to the window group administered by the given window.

### iconify()

Turns the window into an icon, without destroying it.

## protocol(name, function)

Registers a function as a callback which will be called for the given protocol.

### iconify()

Turns the window into an icon, without destroying it.

### state()

and icon. Returns the current state of the window. Possible values are normal, iconic, withdrawn

## transient([master])

window's parent, when no argument is given. Turns the window into a temporary(transient) window for the given master or to the

## withdraw()

Removes the window from the screen, without destroying it.

## maxsize(width, height)

Defines the maximum size for this window.

## minsize(width, height)

Defines the minimum size for this window.

## positionfrom(who)

Defines the position controller.

## resizable(width, height)

Defines the resize flags, which control whether the window can be resized.

## sizefrom(who)

Defines the size controller.

## title(string)

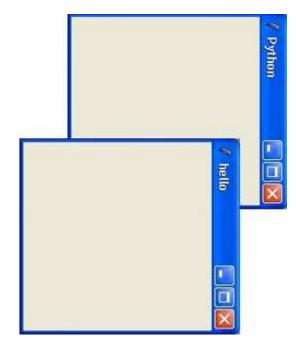

Defines the window title.

### Example

Try following example yourself-

```
top.mainloop()
                                               top = Toplevel()
                    top.title("Python")
                                                                       root.title("hello")
                                                                                                                                                from tkinter import *
                                                                                                root = Tk()
                                                                                                                                                                    !/usr/bin/python3
```

When the above code is executed, it produces the following result-

## Tkinter Spinbox

The Spinbox widget is a variant of the standard Tkinter Entry widget, which can be used to select from a fixed number of values.

### **Syntax**

Here is the simple syntax to create this widget-

```
w = Spinbox(master, option,
```

## **Parameters**

- master: This represents the parent window.
- **options:** Here is the list of most commonly used options for this widget. These options can be used as key-value pairs separated by commas.

ווה ווווווומווו עמומב: ספבמ נסשבנובו אונוו נס נס וווווור נווב שלוווססא	
The minimum value lised together with to to limit the spinhov	from
Format string. No default value.	rormat
The font to use in this widget.	font
Text color.	fg
The text color to use when the widget is disabled.	disabledforeground
The background color to use when the widget is disabled.	disabledbackground
The cursor that appears when the mouse is over the scrollbar.	cursor
A procedure to be called whenever the scrollbar is moved.	command
The width of the 3-d borders around the entire perimeter of the trough, and also the width of the 3-d effects on the arrowheads and slider. Default is no border around the trough, and a 2-pixel border around the arrowheads and slider.	bd
The color of the slider and arrowheads when the mouse is not over them.	bg
The color of the slider and arrowheads when the mouse is over them.	activebackground
Description	Options

justify	Default is LEFT
relief	Default is SUNKEN.
repeatdelay	Together with repeatinterval, this option controls button autorepeat. Both values are given in milliseconds.
repeatinterval	See repeatdelay.
state	One of NORMAL, DISABLED, or "readonly". Default is NORMAL.
textvariable	No default value.
to	See from.
validate	Validation mode. Default is NONE.
validatecommand	Validation callback. No default value.
values	A tuple containing valid values for this widget. Overrides from/to/increment.
vcmd	Same as validatecommand.
width	Widget width, in character units. Default is 20.
wrap	If true, the up and down buttons will wrap around.
xscrollcommand	Used to connect a spinbox field to a horizontal scrollbar. This option should be set to the set method of the corresponding scrollbar.

### **Methods**

Spinbox objects have these methods-

## **Methods and Description**

## delete(startindex [,endindex])

This method deletes a specific character or a range of text.

## get(startindex [,endindex])

This method returns a specific character or a range of text.

## identify(x, y)

Identifies the widget element at the given location.

## index(index)

Returns the absolute value of an index based on the given index.

## insert(index [,string]...)

This method inserts strings at the specified index location.

## invoke(element)

Invokes a spinbox button.

### Example

Try the following example yourself-

```
mainloop()
                                                     w.pack()
                                                                                                                                                                               from Tkinter import *
                                                                                                                               master = Tk()
                                                                            = Spinbox(master, from_=0, to=10)
```

When the above code is execduted, it produces the following result-

## Tkinter PanedWindow

A PanedWindow is a container widget that may contain any number of panes, arranged horizontally or vertically.

Each pane contains one widget and each pair of panes is separated by a moveable (via mouse movements) sash. Moving a sash causes the widgets on either side of the sash to be resized.

### Syntax

Here is the simple syntax to create this widget-

```
Σ
  П
PanedWindow( master,
option,
```

## **Parameters**

- master: This represents the parent window.
- options can be used as key-value pairs separated by commas. options: Here is the list of most commonly used options for this widget. These

Option	Description
bg	The color of the slider and arrowheads when the mouse is not over them.
bd	The width of the 3-d borders around the entire perimeter of the trough, and also the width of the 3-d effects on the arrowheads and slider. Default is no border around the trough, and a 2-pixel border around the arrowheads and slider.
borderwidth	Default is 2.
cursor	The cursor that appears when the mouse is over the window.
handlepad	Default is 8.
handlesize	Default is 8.
height	No default value.
orient	Default is HORIZONTAL.

No default value.	width
No default value	showhandle
Default is 2.	sashwidth
Default is RAISED.	sashrelief
No default value.	sashcursor
Default is FLAT.	relief

### **Methods**

PanedWindow objects have these methods-

## Methods & Description

add(child, options)
Adds a child window to the paned window.

get(startindex [,endindex])
This method returns a specific character or a range of text.

**config(options)**Modifies one or more widget options. If no options are given, the method returns dictionary containing all current option values. а

## Example

Try the following example yourself. Here is how to create a 3-pane widget-

from tkinter import \* !/usr/bin/python3

```
m2.add(bottom)
                                                                                                                                                                                                                           m1.add(m2)
                                                                                                                                                                                                                                                                                                                                                                                                   m1.pack(fill=BOTH, expand=1)
mainloop()
                                                                                  bottom = Button(m2, text="OK")
                                                                                                                                                                     top = Scale( m2, orient=HORIZONTAL)
                                                                                                                                                                                                                                                                                                               m1.add(left)
                                                                                                                                           m2.add(top)
                                                                                                                                                                                                                                                                                                                                                                                                                                 = PanedWindow()
                                                                                                                                                                                                                                                           PanedWindow(m1, orient=VERTICAL)
                                                                                                                                                                                                                                                                                                                                            = Entry(m1, bd=5)
```

When the above code is executed, it produces the following result-

## Tkinter LabelFrame

A labelframe is a simple container widget. Its primary purpose is to act as container for complex window layouts. a spacer or

This widget has the features of a frame plus the ability to display a label.

### Syntax

Here is the simple syntax to create this widget-

```
LabelFrame( master, option,
```

## **Parameters**

master: This represents the parent window.

**options:** Here is the list of most commonly used options for this widget. These options can be used as key-value pairs separated by commas.

Option	Description
bg	The normal background color displayed behind the label and indicator.
bd	The size of the border around the indicator. Default is 2 pixels.
cursor	If you set this option to a cursor name (arrow, dot etc.), the mouse cursor will change to that pattern when it is over the checkbutton.
font	The vertical dimension of the new frame.
height	The vertical dimension of the new frame.
labelAnchor	Specifies where to place the label.
highlightbackground	Color of the focus highlight when the frame does not have focus.
highlightcolor	Color shown in the focus highlight when the frame has the focus.
highlightthickness	Thickness of the focus highlight.
relief	With the default value, relief=FLAT, the checkbutton does not stand out from its background. You may set this option to any of the other styles
text	Specifies a string to be displayed inside the widget.
width	Specifies the desired width for the window.

## Example

Try the following example yourself. Here is how to create a labelframe widget-

# !/usr/bin/python3

from tkinter import \*

```
left
                                                                                                                                                                                                          root
                                                                                                                            labelframe.pack(fill="both", expand="yes")
root.mainloop()
                                                  left.pack()
                                                                                                                                                       labelframe
                                                                            = Label(labelframe,
                                                                                                                                                      = LabelFrame(root,
                                                                             text="Inside
                                                                                                                                                       text="This is
                                                                            the LabelFrame")
                                                                                                                                                        a LabelFrame")
```

When the above code is executed, it produces the following result-

## Tkinter tkMessageBox

The tkMessageBox module is used to display message boxes in your applications. module provides a number of functions that you can use to display an approp message appropriate

Some of these functions are showinfo, showwarning, showerror, askquestion, askokcancel, askyesno, and askretryignore.

### Syntax

Here is the simple syntax to create this widget-

```
tkMessageBox.FunctionName(title,
message
\Box
options])
```

## **Parameters**

- FunctionName: This is the name of the appropriate message box function.
- title: This is the text to be displayed in the title bar of a message box.
- message: This is the text to be displayed as a message
- message box. Some of the options that you can use are default and parent. The options: options are alternative choices that you may use to tailor a standard

IGNORE in the message box. The parent option is used to specify the window on top of which the message box is to be displayed. default option is used to specify the default button, such as ABORT, RETRY, or

You could use one of the following functions with dialogue box-

- showinfo()
- showwarning()
- showerror()
- askquestion()
- askokcancel()
- askyesno ()
- askretrycancel ()

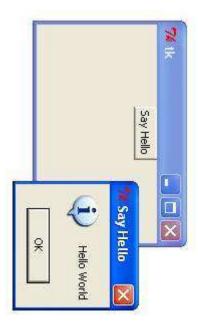

## Example

Try the following example yourself-

```
# !/usr/bin/python3
                                                                   B1.place(x=35,y=50)
                                                                                                   B1 = Button(top, text
                                                                                                                                                                                                      def hello():
                                                                                                                                                                                                                                  top.geometry("100x100")
                                                                                                                                                                                                                                                                                                                                     from tkinter import messagebox
                                                                                                                                                                                                                                                                                                                                                                                                       from tkinter import *
top.mainloop()
                                                                                                                                                                                                                                                                       top = Tk()
                                                                                                                                                                    messagebox.showinfo("Say Hello", "Hello World")
                                                                                                 = "Say Hello", command = hello)
```

When the above code is executed, it produces the following result-

## Standard Attributes

specified. Let us look at how some of the common attributes, such as sizes, colors and fonts are

- Dimensions
- Colors
- Fonts
- Relief styles

Anchors

- Bitmaps
- Cursors

Let us study them briefly-

## **Tkinter Dimensions**

Various lengths, widths, and other dimensions different units. of widgets can be described Ξ. many

- If you set a dimension to an integer, it is assumed to be in pixels.
- followed by. You can specify units by setting a dimension to a string containing a number

Character
Description

Printer's points (about 1/72")	ס
Millimeters	m
Inches	i.
Centimeters	С

## Length options

length options-Tkinter expresses a length as an integer number of pixels. Here <u>s</u>. the list of common

- widget. borderwidth: Width of the border which gives മ three-dimensional look to the
- highlightthickness: Width of the highlight rectangle when the widget has focus
- minimum the widget needs to display its contents in the x and y directions. padX padY: Extra space the widget requests from its layout manager beyond the
- selectborderwidth: Width of the three-dimentional border around selected items of the widget.
- wraplength: Maximum line length for widgets that perform word wrapping
- height: Desired height of the widget; must be greater than or equal to
- underline: Index of the character to underline in the widget's text (0 is the first character, 1 the second one, and so on).
- width: Desired width of the widget.

## **Tkinter Colors**

Tkinter-Tkinter represents colors with strings. There are two general ways ð specify colors ⊒.

- and "#00ffff" You can use a string specifying the proportion of red, green and blue in hexadecimal digits. For example, "#fff" is white, "#000000" is black, "#000fff000" is pure green, is pure cyan (green plus blue).
- available You can also use any locally defined standard color name. "black", "red", "green", "blue", "cyan", "yellow", and "mage name. The "magenta" colors "white", will always be

## Color options

The common color options are-

- activebackground: Background color for the widget when the widget is active.
- activeforeground: Foreground color for the widget when the widget is active
- **background:** Background color for the widget. This can also be represented as bg.
- disabledforeground: Foreground disabled. color for the widget when the widget is
- **foreground:** Foreground color for the widget. This can also be represented as fg.
- highlightbackground: Background color of the highlight region when the widget has focus
- highlightcolor: Foreground color of the highlight region when the widget has
- selectbackground: Background color for the selected items of the widget
- selectforeground: Foreground color for the selected items of the widget

## **Tkinter Fonts**

There may be up to three ways to specify type style.

## **Simple Tuple Fonts**

and overstrike. followed by a string containing one or more of the style modifiers bold, italic, As a tuple whose first element is the font family, followed by a size in points, optionally underline

### Example

- ("Helvetica", "16") for a 16-point Helvetica regular.
- ("Times", "24", "bold italic") for a 24-point Times bold italic

## Font object Fonts

constructor You can create a "font object" by importing the tkFont module and using its Font class

```
font
                   import tkFont
 П
tkFont.Font ( option,
```

Here is the list of options-

- family: The font family name as a string.
- size: The font height as an integer in points. To get a font n pixels high, use -n.
- weight: "bold" for boldface, "normal" for regular weight.
- slant: "italic" for italic, "roman" for unslanted.
- underline: 1 for underlined text, 0 for normal.
- overstrike: 1 for overstruck text, 0 for normal.

### Example

helv36 tkFont.Font(family="Helvetica", size=36, weight="bold")

## X Window Fonts

If you are running under the X Window System, you can use any of the X font names

you select pleasing fonts. the author's favorite fixed-width font for onscreen use. Use thexfontsel program to help For example, the font named "-\*-lucidatypewriter-medium-r-\*-\*-\*-140-\*-\*-\*-\*-" is

## **Tkinter Anchors**

Anchors are used to define where text is positioned relative ₽ ۵ reference point.

Here is list of possible constants, which can be used for Anchor attribute

- NW
- z
- NE
- CENTER

≶

- •
- SW
- S
- SE

and vertically around the reference point. For example, if you use CENTER as a text anchor, the text will be centered horizontally

(top left) corner of the box containing the text. Anchor NW will position the text so that the reference point coincides with the northwest

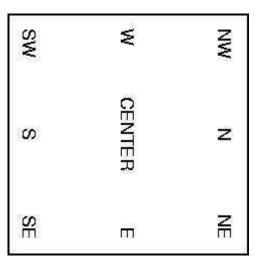

the text box passing through that point, and so on. Anchor W will center the text vertically around the reference point, with the left edge of

widget would be centered along the top edge If you create a small widget inside a large frame and use the anchor=SE option, the widget will be placed in the bottom right corner of the frame. If you used anchor=N instead, the

### Example

The anchor constants are shown in this diagram-

## Tkinter Relief styles

The relief style of a widget refers to certain simulated 3-D effects around the outside of the widget. Here is a screenshot of a row of buttons exhibiting all the possible relief styles-

Here is list of possible constants which can be used for relief attribute-

- FLAT
- RAISED
- SUNKEN
- GROOVE
- RIDGE

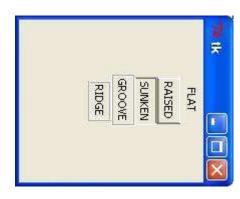

### Example

```
B1 =
                                             top = Tk()
                                                                                                               from tkinter import *
                                                                                          import tkinter
                                                                                                                                     !/usr/bin/python3
Button(top, text ="FLAT",
   relief=FLAT )
```

```
top.mainloop()
              B5.pack()
                             B4.pack()
                                            B3.pack()
                                                          B2.pack()
                                                                          B1.pack()
                                                                                                                        В4
                                                                                                                                       ВЗ
                                                                                                                                                      В2
                                                                                                                                     = Button(top,
                                                                                                        Button(top,
                                                                                                                      Button(top,
                                                                                                                                                   Button(top,
                                                                                                                                                      text
                                                                                                        text ="RIDGE", relief=RIDGE )
                                                                                                                        text
                                                                                                                                      text ="SUNKEN",
                                                                                                                       ="GROOVE",
                                                                                                                                                     ="RAISED",
                                                                                                                                      relief=SUNKEN )
                                                                                                                                                      relief=RAISED
                                                                                                                        relief=GROOVE
```

When the above code is executed, it produces the following result-

## Tkinter Bitmaps

This attribute to displays a bitmap. There are following type of bitmaps available-

- "error"
- "gray75"
- "gray50"
- "gray25"
- "gray12"
- "hourglass"
- "info"

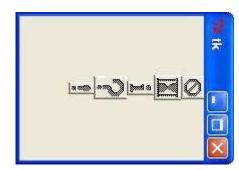

- "questhead"
- "question"
- "warning"

### Example

```
top.mainloop()
                         B5.pack()
                                                  B4.pack()
                                                                           B3.pack()
                                                                                                     B2.pack()
                                                                                                                             B1.pack()
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        # !/usr/bin/python3
                                                                                                                                                                                                             В5
                                                                                                                                                                                                                                                              В4
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       import tkinter
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              from tkinter import *

                                                                                                                                                                                                                                                          ="question", relief=RAISED,\
                                                                                                                                                                                                                                                                                     bitmap="info")
                                                                                                                                                                                                                                                                                                                                                                                       bitmap="error")
                                                                                                                                                                                 bitmap="warning")
                                                                                                                                                                                                                                 bitmap="question")
                                                                                                                                                                                                                                                                                                                                      bitmap="hourglass")
```

When the above code is executed, it produces the following result-

## Tkinter Cursors

Here is the list of interesting ones-

- "arrow"
- "circle"
- "clock"
- "cross"
- "dotbox"
- "exchange"
- "fleur"
- "heart"
- "heart"
- "man" "mouse"
- "pirate"
- "plus"
- "shuttle"
- "sizing"
- "spider"
- "spraycan"
- "star"
- "target"
- "tcross"
- "trek"
- "watch"

### Example

Try the following example by moving cursor on different buttons-

```
B1.pack()
                   B2.pack()
                                                                             В2
                                                                                                                  В1
                                                                                                                                                                                            import tkinter
                                                                                                                                                                                                                                # !/usr/bin/python3
top.mainloop()
                                                                                                                                                       top =
                                                                                                                                                                                                               from tkinter import *
                                                                              П
                                                                           Button(top,
                                                                                                               Button(top,
                                                                                                                                                       Tk()
                                                                                                                text
                                                                           text ="plus",
                                                                                                               ="circle", relief=RAISED,\
                                                                                             cursor="circle")
                                                        cursor="plus")
                                                                           relief=RAISED,\
```

## Geometry Management

exposes the following geometry manager classes: pack, grid, and place. have the purpose of organizing widgets throughout the parent widget area. All Tkinter widgets have access to the specific geometry management methods, Tkinter which

- placing them in the parent widget. The pack() Method - This geometry manager organizes widgets in blocks before
- structure in the parent widget. The grid() Method - This geometry manager organizes widgets Ξ. മ table-like
- a specific position in the parent widget. The place() Method -This geometry manager organizes widgets by placing them in

Let us study the geometry management methods briefly

## Tkinter pack() Method

This geometry manager organizes widgets widget. in blocks before placing them Ξ. the parent

### Syntax

```
widget.pack( pack_options
```

Here is the list of possible options-

- widget's parent. expand: When set to true, widget expands to fill any space not otherwise used in
- **fill:** Determines whether widget fills any extra space allocated to it by the packer, or keeps its own minimal dimensions: NONE (default), X (fill only horizontally), Y (fill only vertically), or BOTH (fill both horizontally and vertically).
- BOTTOM, LEFT, or RIGHT. side: Determines which side of the parent widget packs against: TOP (default),

## Example

Try the following example by moving cursor on different buttons-

```
frame
                                                                                                                                                                                                                                                                                                                                                   root

                                                                                                                                                                     Button(frame, text="Red",
                                                                                                                                                                                                                                                = Frame(root)
                       Button(frame, text="Blue",
                                                                                              Button(frame, text="Brown", fg="brown")
                                                                                                                                                   II
  П
                                                                                                                                                 LEFT)
 LEFT )
                                                                                                                                                                        fg="red")
                       fg="blue")
```

```
blackbutton.pack( side = BOTTOM)
root.mainloop()
                                                                               blackbutton
                                                                              = Button(bottomframe,
                                                                             text="Black",
                                                                             fg="black")
```

When the above code is executed, it produces the following result-

## Tkinter grid() Method

This geometry manager organizes widgets Ξ. а table-like structure in the parent widget.

### **Syntax**

```
widget.grid(
grid_options
```

Here is the list of possible options-

- column: The column to put widget in; default 0 (leftmost column).
- columnspan: How many columns widgetoccupies; default 1
- ipadx, ipady: How many pixels to pad widget, horizontally and vertically, inside widget's borders.
- v's borders **padx, pady**:How many pixels to pad widget, horizontally and vertically, outside
- row: The row to put widget in; default the first row that is still empty.
- rowspan: How many rowswidget occupies; default 1.
- of N, E, S, W, NE, NW, SE, and SW, compass directions indicating the sides and widget is centered in its cell. sticky may be the string concatenation of zero or more sticky: What to do if the cell is larger than widget. By default, with sticky=" corners of the cell to which widget sticks.

## Example

Try the following example by moving cursor on different buttons

```
root
                              # !/usr/bin/python3
  П
               tkinter import
Tk(
```

```
for
                                                                                                                      b=0
root.mainloop()
                                                                                                 7
                                                                              for
                                                                                              in range(6):
                                                                              0
                                       Button(root, text=str(b),
                                                            b=b+1
                                                                            in range(6):
                  borderwidth=1 ).grid(row=r,column=c)
```

This would produce the following result displaying 12 labels arrayed in a ω  $\times$ 4 grid-

## Tkinter place() Method

parent widget. This geometry manager organizes widgets by placing them in a specific position in the

### Syntax

```
widget.place( place_options
```

Here is the list of possible options-

- default is NW (the upper left corner of widget) **anchor**: The exact spot of widget other options refer to: may be N, E, S, W, NE, NW, SE, or SW, compass directions indicating the corners and sides of widget;
- **bordermode**: INSIDE (the default) to indicate that other optic parent's inside (ignoring the parent's border); OUTSIDE otherwise. (the default) to indicate that other options refer to the
- height, width: Height and width in pixels.
- fraction of the height and width of the parent widget. relheight, relwidth: Height and width as a float between 0.0 and 1.0, as ۵
- **relx, rely:** Horizontal and vertical offset as a float between 0.0 and 1.0, fraction of the height and width of the parent widget. as а
- x, y: Horizontal and vertical offset in pixels.

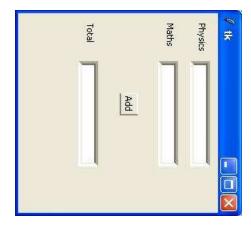

## Example

Try the following example by moving cursor on different buttons-

```
B.place(x=100, y=100)
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            # !/usr/bin/python3
top.mainloop()
                         top.geometry("250x250+10+10")
                                                                                                                                      E3.place(x=60,y=150)
                                                                                                                                                                  E3=Entry(top,bd=5)
                                                                                                                                                                                                                                                                              E2.place(x=60,y=50)
                                                                                                                                                                                                                                                                                                       E2=Entry(top,bd=5)
                                                                                                                                                                                                                                                                                                                                                                                        E1.place(x=60,y=10)
                                                                                                                                                                                                                                                                                                                                                                                                                  E1 = Entry(top, bd =5)
                                                                                                                                                                                                                                                                                                                                                                                                                                               L1.place(x=10,y=10)
                                                                                                                                                                                                                                                                                                                                                                                                                                                                          L1 = Label(top, text="Physics")
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        top =
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                 ffrom tkinter import *
                                                                                                                                                                                             L3.place(x=10,y=150)
                                                                                                                                                                                                                     L3=Label(top,text="Total")
                                                                                                                                                                                                                                                                                                                                    L2.place(x=10,y=50)
                                                                                                                                                                                                                                                                                                                                                              L2=Label(top,text="Maths")
                                                                               Button(top, text ="Add")
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        Tk()
```

When the above code is executed, it produces the following result-

# 28. Python 3 — Extension Programming with C

Any code that you write using any compiled language like C, C++, or Java can integrated or imported into another Python script. This code is considered as "extension." an be

see .dll (for dynamically linked library). these libraries usually end in .so (for shared object). On Windows machines, you typically A Python extension module is nothing more than a normal C library. On Unix machines,

## **Pre-Requisites for Writing Extensions**

To start writing your extension, you are going to need the Python header files

- as python2.5-dev On Unix machines, this usually requires installing a developer-specific package such
- Python installer. Windows users get these headers as part of the package when they use the binary

Python Extension using C programming. Additionally, it is assumed that you have ۵ good knowledge of C or C++ to write any

## First look at a Python Extension

For your first look at a Python extension module, you need to group your code into four

- The header file Python.h.
- The C functions you want to expose as the interface from your module
- functions inside the extension module. A table mapping the names of your functions as Python developers see them as  $\cap$
- An initialization function.

## The Header File Python.h

to the internal Python API used to hook your module into the interpreter. You need to include Python.h header file in your C source file, which gives you the access

Make sure to include Python.h before any other headers you might need. You need to follow the includes with the functions you want to call from Python.

## The C Functions

of the following

```
static PyObject *MyFunctionWithNoArgs( PyObject *self );
                                                                                                                            static PyObject *MyFunctionWithKeywords(PyObject
                                                                                                                                                                                          static PyObject
                                                                                                                                                                                          *MyFunction( PyObject
                                                            PyObject *kw);
                                                                                             PyObject *args,
                                                                                                                                                                                          *self,
                                                                                                                                                                                           Py0bject
                                                                                                                            *self,
                                                                                                                                                                                          *args
```

Py\_RETURN\_NONE, that does this for us. value, return the C equivalent of Python's **None** value. The Python headers define a macro, a void function in Python as there is in C. If you do not want your functions to return a Each one of the preceding declarations returns a Python object. There is no such thing as

the extension module. They are defined as static function. The names of your C functions can be whatever you like as they are never seen outside of

together, as shown here Your C functions usually are named by combining the Python module and function names

```
static PyObject *module_func(PyObject *self, PyObject *args)
Py_RETURN_NONE;
                                                   /* Do your stuff here. */
```

to your C functions into the method table for the module that usually comes next in your source code. This is a Python function called func inside the module module. You will be putting pointers

## The Method Mapping Table

something like this-This method table <u>s</u>. മ simple array of PyMethodDef structures. That structure looks

```
۲.
                                                                                                            struct PyMethodDef
                      char *ml_doc;
                                          int ml_flags;
                                                                 PyCFunction ml_meth;
                                                                                     char *ml_name;
```

Here is the description of the members of this structure-

- when it is ml\_name: This is the name of the used in Python programs function as the Python interpreter presents
- ml\_meth: This is the address of a function that has any one of the signatures, described in the previous section.
- **ml\_flags:** This tells the interpreter which of the three signatures ml\_meth is using.
- This flag usually has a value of METH\_VARARGS
- 0 keyword arguments into your function. This flag can be bitwise OR'ed with METH\_KEYWORDS if you want to allow
- 0 to accept any arguments. This can also have a value of METH\_NOARGS that indicates you do not want
- ml\_doc: This is the docstring for the function, which could be NULL if you do not feel like writing one

This the appropriate members table needs to be terminated with a sentinel that consists of NULL and 0 values for

### Example

For the above-defined function, we have the following method mapping table-

```
۲.
                                                                                                          static PyMethodDef module_methods[] =
                                   NULL, NULL,
                                                                      "func", (PyCFunction) module_func, METH_NOARGS, NULL
                                    0, NULL
```

## The Initialization Function

named initModule, where Module is the name of the module. by the Python interpreter when the module is The last part of your extension module is the initialization function. This function is called loaded. It is required that the function be

Python headers define PyMODINIT\_FUNC to include the appropriate incantations for that use it when defining the function. to happen for the particular environment in which we are compiling. All you have to do is The initialization function needs to be exported from the library you will be building. The

 $\cap$ initialization function generally has the following overall structure

```
PyMODINIT_FUNC initModule() {
 Py_InitModule3(func,
module_methods, "docstring...");
```

Here is the description of Py\_InitModule3 function-

- func: This is the function to be exported.
- module\_methods: This is the mapping table name defined above.
- docstring: This is the comment you want to give in your extension.

Putting all this together, it looks like the following-

```
۲,
                                                                                                                                                                                                                                                                                      static PyMethodDef module_methods[] =
                                               PyMODINIT_FUNC initModule() {
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    static PyObject *module_func(PyObject *self, PyObject *args) {
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       #include <Python.h>
                                                                                                                                                                                                                                                                                                                                                                                                                                      Py_RETURN_NONE;
Py_InitModule3(func, module_methods, "docstring...");
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       /* Do your stuff here. */
                                                                                                                                                                                                                                         "func", (PyCFunction) module_func, METH_NOARGS, NULL },
                                                                                                                                                                                            NULL, NULL, 0, NULL }
```

### Example

A simple example that makes use of all the above concepts-

```
static PyMethodDef helloworld_funcs[] =
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      #include <Python.h>
                                                                                                                                                                                                                                                                                    static char helloworld_docs[] =
                                                {"helloworld", (PyCFunction)helloworld,
                                                                                                                                                                                                                          "helloworld( ): Any message you want to put here!!\n";
                                                                                                                                                                                                                                                                                                                                                                                                                                                       return Py_BuildValue("s", "Hello, Python extensions!!");
METH_NOARGS, helloworld_docs},
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   PyObject* helloworld(PyObject* self)
```

```
void
                                                                                                                                                                 ۲.
                                Py_InitModule3("helloworld", helloworld_funcs,
                                                                                                 inithelloworld(void)
"Extension module example!");
```

file. We would see how to compile and install this module to be called from Python script. Here the Py\_BuildValue function is used to build a Python value. Save above code in hello.c

## **Building and Installing Extensions**

built and installed via a setup script usually called setup.pyas. and extension modules, in a standard way. Modules are distributed in The distutils package makes it very easy to distribute Python modules, both pure Python the source form,

For the above module, you need to prepare the following setup.py script

```
setup(name='helloworld', version='1.0',
                                                                                                                                     from distutils.core import setup, Extension
ext_modules=[Extension('helloworld', ['hello.c'])])
```

steps, with the right compiler and linker commands and flags, and copies the resulting Now, use the following command, which would perform all needed compilation and linking dynamic library into an appropriate directory-

```
python setup.py install
```

Windows. On Unix-based systems, you will most likely need to run this command as root in order to have permissions to write to the site-packages directory. This usually is not a problem on

## Importing Extensions

Once you install your extensions, you would be able to import and call that extension in your Python script as follows-

```
print helloworld.helloworld()
                                                                           import helloworld
                                                                                                                #!/usr/bin/python3
```

This would produce the following result-

```
Hello, Python extensions!!
```

## Passing Function Parameters

As you will most likely want to define functions that accept arguments, you can use of the other signatures for your C functions. For example, the following function, accepts some number of parameters, would be defined like thisfollowing function, that one

```
static PyObject *module_func(PyObject *self, PyObject *args)
Py_RETURN_NONE;
                                                /st Parse args and do something interesting here.
                                                        *
```

The method table containing an entry for the new function would look like this-

```
static
                                                              { "func",
{ NULL, NULL,
                            { "func", module_func, METH_VARARGS, NULL },
                                                                                                    PyMethodDef module_methods[] =
                                                                (PyCFunction) module_func, METH_NOARGS, NULL },
0, NULL
```

PyObject pointer passed into your C function. You can use the API PyArg\_ParseTuple function ţ extract the arguments from the one

expect them to appear. format string as follows. be parsing. The second The first argument to PyArg\_ParseTuple is the args argument. This is the object you will Each argument is represented by one or more characters in the argument is a format string describing the arguments as

```
static PyObject *module_func(PyObject *self, PyObject *args) {
                                                                                                                                                                                                                                                                                                                    int i;
                                                                                                                                                                                                                                                char *s;
Py_RETURN_NONE;
                                                                                                                                                                                                                                                                                    double d;
                                  Do something interesting here.
                                                                                                                                           return NULL;
                                                                                                                                                                         (!PyArg_ParseTuple(args,
                                                                                                                                                                          "ids", &i, &d, &s)) {
```

function with any number of arguments of any type-Compiling the new version of your module and importing it enables you to invoke the new

```
module.func(i=1, d=2.0, s="three")
                          module.func(1,
                          s="three",
                            d=2.0)
```

```
module.func(s="three", d=2.0, i=1)
```

You can probably come up with even more variations.

## The PyArg\_ParseTuple Function

Here is the standard signature for the **PyArg\_ParseTuple** function=

```
int PyArg_ParseTuple(PyObject* tuple,char* format,...)
```

describes mandatory and optional arguments. This function returns 0 for errors, and a value not equal to 0 for success. Tuple is the PyObject\* that was the C function's second argument. Here *format* is a C string that

Here is a list of format codes for the **PyArg\_ParseTuple** function-

u#	n	#1	#8	S	0	Т			Ą	р	С	Code
Py_UNICODE*+int	Py_UNICODE*	char*+int	char*+int	char*	PyObject*	long long	long	int	float	double	char	C type
Any Python Unicode C address and length.	Python Unicode without embedded nulls to C.	Read-only single-segment buffer to C address and length.	Any Python string to C address and length.	Python string without embedded nulls to C char*.	Gets non-NULL borrowed reference to Python argument.	A Python int becomes a C long long	A Python int becomes a C long.	A Python int becomes a C int.	A Python float becomes a C float.	A Python float becomes a C double.	A Python string of length 1 becomes a C char.	Meaning

Format end, followed by entire error message text.		~-
Format end, followed by function name for error messages.		
The following arguments are optional.		_
A Python sequence is treated as one argument per item.	as per	()
Like s#, also accepts None (sets C char* to NULL).	char*+int	Z#
Like s, also accepts None (sets C char* to NULL).	char*	Z
Read/write single-segment buffer to C address and length.	char*+int	W#

## **Returning Values**

passing in the addresses of the values you are building, you pass in the actual values. Here is an example showing how to implement an add function-Py\_BuildValue takes in a format string much like PyArg\_ParseTuple does. Instead of

```
static PyObject *foo_add(PyObject *self, PyObject *args) {
                                                                                                                                       int b;
                                                                                                                                                               int a;
return Py_BuildValue("i", a
                                                                                   Ť
                                                                              (!PyArg_ParseTuple(args, "ii", &a, &b)) {
                                                        return NULL;
  +
 ь);
```

This is what it would look like if implemented in Python-

```
def add(a, b):
return (a + b)
```

You can return two values from your function as follows. This would be list in Python. captured using

```
static PyObject *foo_add_subtract(PyObject *self, PyObject *args) {
                                              int a;
                     int b;
497
```

```
return Py_BuildValue("ii",
                                                  Ť
                                               (!PyArg_ParseTuple(args, "ii", &a, &b)) {
                                return NULL;
  a
  +
  ٩
  a
;(d
```

This is what it would look like if implemented in Python-

```
def add_subtract(a,
return (a + b, a - b)
                        <u>ь</u>):
```

## The Py\_BuildValue Function

Here is the standard signature for Py\_BuildValue function-

```
PyObject* Py_BuildValue(char* format,...)
```

Here format is a C string that describes the Python object to build. The following arguments of  $Py\_BuildValue$  are C values from which the result is built. The PyObject\* result is a new reference.

into a string format. The following table lists the commonly used code strings, of which zero or more are joined

Code	C type	Meaning
С	char	A C char becomes a Python string of length 1.
р	double	A C double becomes a Python float.
Ť	float	A C float becomes a Python float.
	int	A C int becomes a Python int.
	long	A C long becomes a Python int.
Z	PyObject*	Passes a Python object and steals a reference.
0	PyObject*	Passes a Python object and INCREFs it as normal.
0&	convert+void*	Arbitrary conversion

S	char*	${\sf C}$ 0-terminated char* to Python string, or NULL to None.
**	char*+int	C char $st$ and length to Python string, or NULL to None.
C	Py_UNICODE*	C-wide, null-terminated string to Python Unicode, or NULL to None.
u#	Py_UNICODE*+int	C-wide string and length to Python Unicode, or NULL to None.
w#	char*+int	Read/write single-segment buffer to C address and length.
Z	char*	Like s, also accepts None (sets C char* to NULL).
Z#	char*+int	Like s $\#$ , also accepts None (sets C char $*$ to NULL).
()	as per	Builds Python tuple from C values.
[]	as per	Builds Python list from C values.
{}	as per	Builds Python dictionary from C values, alternating keys and values.
Code {	.} builds dictionaries	Code {} builds dictionaries from an even number of C values, alternately kevs and

Code {...} builds dictionaries from an even number of C values, alternately keys and values. For example, Py\_BuildValue("{issi}",23,"zig","zag",42) returns a dictionary like Python's {23:'zig','zag':42}.
